FIGURE 21-43 Moebius syndrome (congenital facial diplegia). **A** and **B**, Two coronal CT images from anterior to posterior showing a small right geniculate ganglion (*black arrow* in **A**) and a small tympanic segment of the right facial nerve (*black arrow* in **B**). Also note the stenotic oval window (*white arrow* in **B**). **C** and **D,** One mm coronal CT images from anterior to posterior showing a normal left geniculate ganglion (*black arrow* in **C**) and a normal tympanic segment of the left facial nerve (*black arrow* in **D**) and a normal left oval window (*white arrow* in **D**). The soft tissue in the left EAC is postoperative.

in adults. Coronal CT of the petrous pyramid typically demonstrates incomplete development of the tegmen tympani, and there may be an associated meningocele or meningoencephalocele protruding into the middle ear. Treatment consists of neurosurgical repair of the bone and meningeal defects.

Small arachnoid granulations can occur not only in the tegemen but in any plate of bone separating the mastoid or petrous air cells from the CSF. Rarely, CSF can ''break through'' into the air-containing structures.

Hyrtl's Fissure

Hyrtl's fissure is an embryonic remnant that can rarely remain patent and, when present, opens inferior to the round window niche. It runs parallel to the cochlear aqueduct and extends along the inferior aspect of the cochlea connecting the hypotympanum with the posterior fossa at the jugular fossa. Gacek and Leipzig[93] described a large meningocele of the middle ear that extended through Hyrtl's fissure in a patient presenting with CSF otorrhea following a myrigotomy for serous otitis media. Phelps described two similar cases.[84]

Fissula Antefenestram

The fissula antefenestram is a microfissure like Hyrtl's fissure. It is an appendage of the perilymphatic labyrinth. It consists of periotic connective tissue that extends from the vestibule anterior to the oval window through a slit-like space in the otic capsule into the middle ear near the cochleariform process. In a large series of 331 temporal bones, 25% were found to have microfissures near the round window, and Hyrtl's fissure and the fissula antefenestram were among those most commonly seen.[94]

Giant Apical Air Cell and Apical Meningocele

Kraus and McCabe[95] described a dehiscence in the medial wall of the middle ear anterior to the cochlea. The defect contained ruptured pulsating arachnoid, and there was a copious CSF leak into the middle ear cavity and eustachian tube resulting in CSF rhinorrhea. A large air cell in the petrous apex can have very thin bone separating the air space from the CSF. An arachnoid granulation may potentially perforate into this air space, allowing it to fill with CSF. Dilated or giant air cells can be seen in the petrous bone as an isolated finding without CSF leak as well.

Copyright © 2003, Mosby, Inc. All rights reserved.

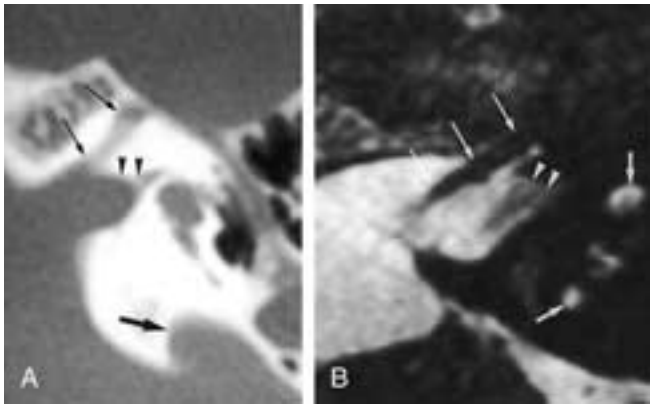
An apical meningocele is a CSF-filled space in the apex of the petrous bone. Usually it communicates with the CSF space in Meckel's cave. Such a collection may be seen as an incidental finding or it may communicate with the middle ear, resulting in a CSF leak. The cavity may be rounded and apparently slightly expanded, mimicking a cholesterol cyst on CT. The density is characteristic of CSF and is low. On MR imaging, the fluid follows a signal pattern of CSF rather than having the high signal on T1-weighted images characteristic of cholesterol granuloma (cyst). These abnormalities are usually seen in the elderly and are not truly congenital. They may be the result of softening of the thin bone.

Petromastoid Canal

The petromastoid canal is a canal parallel and superior to the IAC that carries the subarcuate vessels beneath the superior semicircular canal to the periantral mastoid air cells. It has been proposed but not proven to be a potential route for fistulas or meningitis.[3, 84]

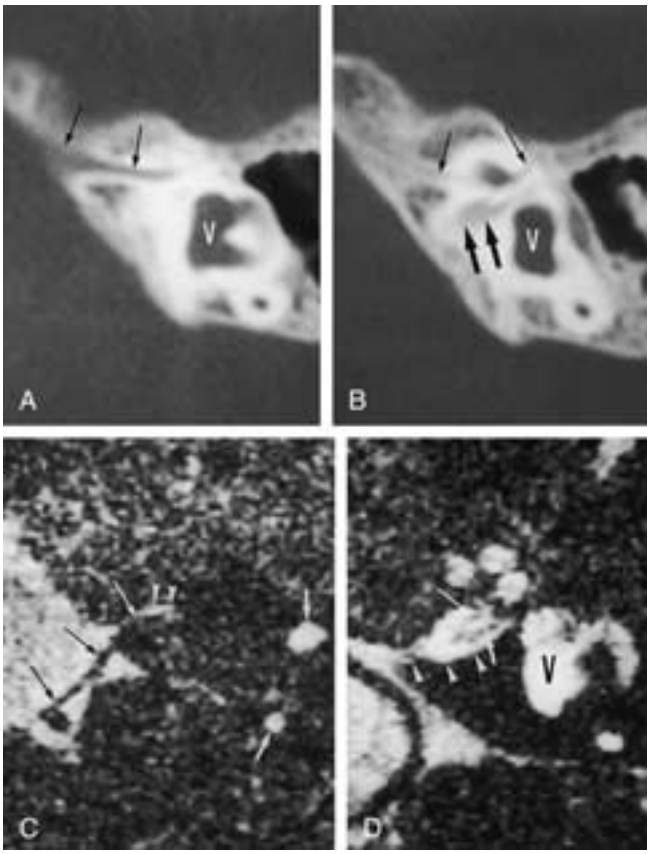
Widened Labyrinthine Segment of the Facial Nerve Canal

There have been a few case reports of CSF fistulas occurring through abnormal lateral extension of the subarachnoid space following the labyrinthine segment of the facial nerve to the geniculate turn, thereby producing a potential CSF fistula directly into the middle ear cavity (Fig. 21-65).[84, 93, 96, 97] These cases have been reported in patients with normal labyrinths, although, CSF fistulas of this type may also occur in patients with anomalies of the labyrinth.[84]



VIEW IMAGE

FIGURE 21-44 Facial nerve leaving the IAC in its middle one third in a patient with bilateral congenital deafness. **A**, Axial CT image through the right IAC. The labyrinthine segment of the facial nerve canal (*long black arrows*) leaves the IAC in its middle one third. Fundus of the IAC (*black arrowheads*), large vestibular aqueduct (*large black arrow*). **B**, Axial T2-weighted gradient-echo image through the right IAC. The facial nerve (*long white arrows*) can be followed from the IAC into the long labyrinthine segment of the facial nerve canal. Fluid in the fundus of the IAC (*white arrowheads*) and fluid in the branches of the superior semicircular duct (*small white arrows*). The presence of CSF between the facial nerve and the walls of the labyrinthine segment of the facial nerve canal, together with the presence of a large vestibular aqueduct on CT, are findings that should alert the examiner to the presence of a gusher ear.



VIEW IMAGE

FIGURE 21-45 Facial nerve running in a separate canal parallel to the IAC. **A** and **B**, Axial CT image made above the left cochlea (**A**) and at the level of the upper part of the left cochlea and through the IAC (**B**). **A**, A separate canal for the facial nerve can be seen high and anteriorly in the left temporal bone (*long black arrows*). *V*, vestibule. **B**, The facial nerve canal can be followed posterior to the upper part of the cochlea (*long black arrows*). The IAC can now also be seen (*large black arrows*). *V*, vestibule. **C** and **D**, Axial 0.7 mm thick 3DFT-CISS images made at the level of the superior semicircular duct (**C**) and IAC (**D**). **C**, In the cerebellopontine angle, the facial nerve can be found in a high and anterior position (*long black arrows*) and continues its course in a separate facial nerve canal (*long white arrow*). Fluid in the labyrinthine segment of the facial nerve canal (*white arrowheads*) and fluid in the branches of the superior semicircular duct (*small white arrows*). **D**, The cochlear branch (*long white arrow*) and inferior vestibular branch (*small white arrow*) of the eighth nerve can be seen in the CSF-filled IAC (*white arrowheads*). *V,* Vestibule.

Translabyrinthine Fistulas

Translabyrinthine fistulas may occur through deficiencies in the lamina cribrosa, a thin, bony layer separating the apex of the IAC from the vestibule, or through deficiencies in the cochlear modiolus (Fig. 21-64B). These deficiencies allow a communication between the CSF in the IAC with the perilymph in the vestibule or cochlea, resulting in increased hydrostatic pressure within the inner ear, a condition known as *perilymphatic hydrops*.[4, 85] Perilymphatic hydrops may result in displacement and/or perforation of the stapes footplate, allowing CSF and perilymph to enter the middle ear cavity through the oval window. This transmission of CSF and perilymph into the middle ear cavity may occur spontaneously. In the past, surgical manipulation of the stapes for presumed fixation resulted in an acute outpouring of fluid known as the *stapes gusher*. Although fistulous

communication through the round window is also possible, it is much less common. Of note, not all cochlear dysplasias are associated with translabyrinthine fistulas. Mondini dysplasias were previously thought to be associated with these fistulas, but in fact, the intact modiolar base in Mondini dysplasias may prevent a fistulous communication between CSF in the IAC and perilymph in the cochlea.[84, 98]

Another route that has been proposed for translabyrinthine fistulas is the wide cochlear aqueduct. The cochlear aqueduct extends from the subarachnoid space medially, where the orifice lies between the IAC superiorly and the jugular foramen posteriorly, to the cochlea, opening laterally close to the round window membrane. It is a bony channel that houses the perilymphatic duct. Many anatomists believe that there is not a true open lumen, but rather that loose connective tissue fills the aqueduct, and thus that there is only a potential communication between the perilymph and the CSF.[99] It is generally accepted that the cochlear aqueduct is functionally patent in animals and young children, but there is controversy regarding its patency in adult life.[100] Persistent patency or enlargement of the aqueduct or a deficiency in the connective tissue within the duct might allow for the development of perilymphatic hydrops and a translabyrinthine fistula. However, this theory has been called into question.[84] This proposed route has not been documented with contrast or radiolabeled isotopes,[101] and cochlear aqueduct ablation in patients with presumed fistulas via an enlarged aqueduct has not succeeded in obliterating the fistula.[102]

What defines an enlarged cochlear aqueduct is not clear. In a study by Jackler and Hwang,[100] the cochlear aqueduct was divided into four parts, which were, from medial to lateral, a medial aperture into the posterior fossa; a petrous apex segment; an otic capsule segment; and a lateral orifice into the cochlea. They found great variability in the medial aperture ranging from 0 to 11 mm in normal subjects, with a mean of 4.5 mm. The measurements called into question previous reports of enlarged medial apertures.[102, 103] In contrast, the otic capsule segment was very narrow in every case, not visualized in some and never exceeding 2 mm in diameter. The authors stated that the narrowest segment should dictate whether or not CSF flow through the duct was possible, not the widest segment, which is usually the medial aperture. They therefore recommended that the radiographic criterion for cochlear aqueduct enlargement be established as the duct's exceeding 2 mm in diameter through its course from the posterior fossa to the inner ear. In fact, the otic segment of the duct actually averages less than 0.2 mm,

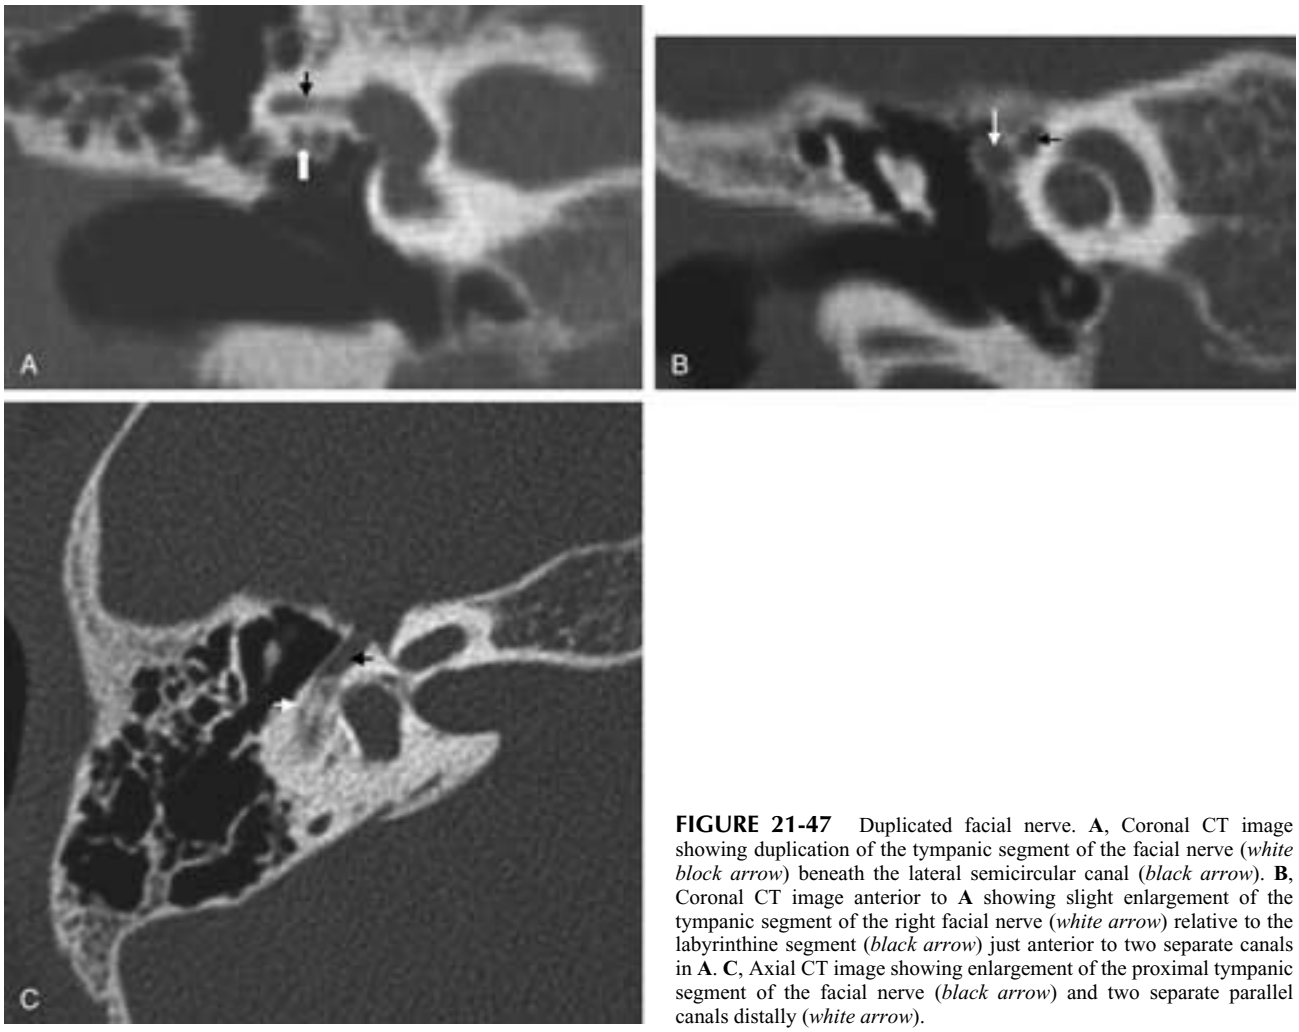

FIGURE 21-47 Duplicated facial nerve. **A**, Coronal CT image showing duplication of the tympanic segment of the facial nerve (*white block arrow*) beneath the lateral semicircular canal (*black arrow*). **B**, Coronal CT image anterior to **A** showing slight enlargement of the tympanic segment of the right facial nerve (*white arrow*) relative to the labyrinthine segment (*black arrow*) just anterior to two separate canals in **A**. **C**, Axial CT image showing enlargement of the proximal tympanic segment of the facial nerve (*black arrow*) and two separate parallel canals distally (*white arrow*).

Immediately anteriorly, there is another facial nerve in its own separate canal (*thin black arrow*). **B**, Axial CT image showing the thickened modiolus (*black arrow*). **C**, Sagittal oblique reconstructed high-resolution, T2-weighted MR image showing five instead of four nerves in the IAC secondary to duplication of the facial nerve (*black arrows*).

VIEW IMAGE

currently below the limit of resolution with CT. Jackler et al.'s recommendation for an enlarged aqueduct is limited by the fact that submillimeter increments in duct diameter may be significant and again below the limit of resolution with CT, and by the fact that deficiencies in the connective tissue within the canal would not likely be manifested as canal enlargement.

CONGENITAL SYNDROMES INVOLVING THE EAR

Syndromes associated with congential anomalies of the ear are often the result of an inherited disorder, although substrate damage in utero as a result of an external teratogen may also occur. The hearing loss associated with these syndromes tends to be severe and is less responsive to correction because the onset is early and significant architectural anomalies are present.

These syndromes may be classified and organized in a variety of ways. They may be organized according to their Mendelian inheritance pattern: autosomal dominant, autosomal recessive, or sex-linked. Some syndromes are the result of a chromosomal aberration, either augmentation or deletion. In utero exposure to certain drugs or teratogens may result in specific anomalies. Still other syndromes are the result of an interaction of genetic factors with environmental influences and can be categorized as ''multifactorial genetic disorders.''[104] Others may be classified according to common clinical and radiologic features. For example, certain syndromes that involve the ear may also have associated craniofacial, cervical, or skeletal anomalies.[105] In the otocraniofacial group, the syndromes may share anomalies of the ear, skull, and face. Many of these are of autosomal dominant inheritance and have anomalies primarily of the outer ear and middle ears or anomalies of structures derived from the first and second branchial arches, with only occasional inner ear anomalies. In the otocervical

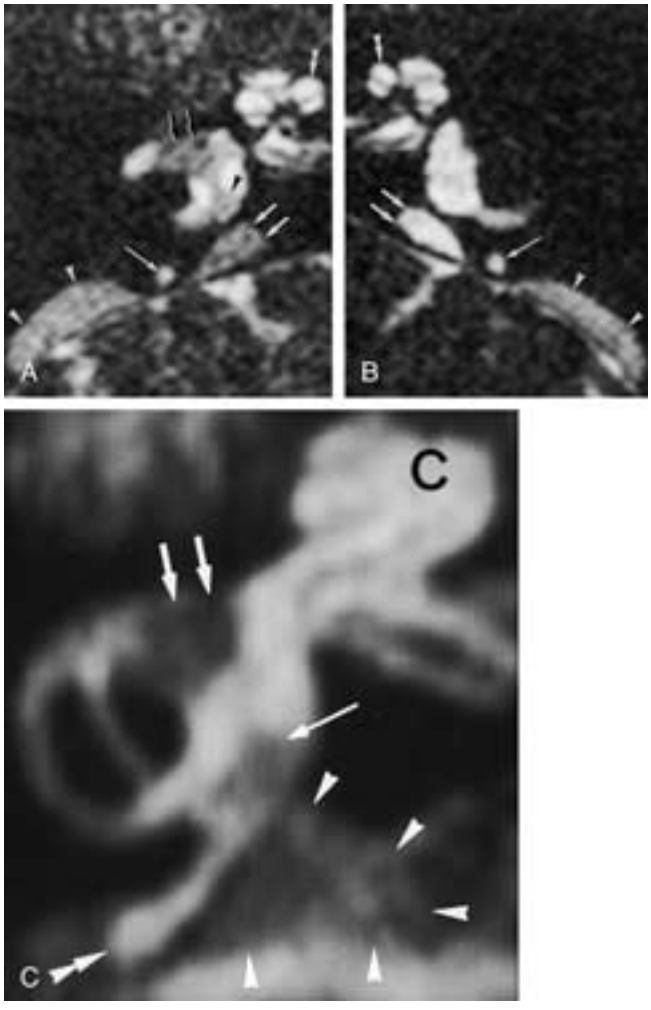
FIGURE 21-52 Large endolymphatic duct and sac with asymmetry of the cochlear scalar chambers. Axial T2-weighted gradient-echo image through the right cochlea and vestibule. The large endolymphatic sac (*white arrowheads*) can be separated from the CSF in the posterior fossa because the dura mater (*long black arrow*) can be distinguished on MR imaging. The scala vestibuli/media (*small white arrow*) is two to three times larger than the scala tympani (*long white arrow*), which is abnormal. Normally, both scalas have the same size (see Figs. 21-25A,C and 21-51D). The modiolus is dysplastic and small (*small black arrow*), another frequent finding in patients with large endolymphatic sacs and ducts. Normal posterior semicircular duct (*double arrowhead*) and vestibule (*V*).



VIEW IMAGE

FIGURE 21-53 Pendred syndrome: bilateral large endolymphatic sac and duct, with loss of normal fluid in the endolymphatic sac on both sides and in the endolymphatic duct and vestibule on the right side. **A**, Axial 0.7 mm gradient-echo T2-weighted image through the right inner ear. The endolymphatic duct (*small white arrows*) and sac (*white arrowheads*) are enlarged, and the fluid in these enlarged structures is replaced by low signal intensity soft tissues. Similar signal changes occurred in the ampulla of the lateral semicircular duct (*small black arrows*) and in the posterior part of the vestibule (*black arrowhead*). This lower signal can represent fibrous tissue or loose vascular subepithelial connective tissue and cuboidal to columnar epithelial cells, also called the *rugose* portion. Note that the scala vestibuli/media (*double arrowhead*) is again larger than the scala vestibuli. The asymmetry of the cochlear chambers is, however, less pronounced than in Figure 21-52. Normal fluid inside the posterior semicircular duct (*long white arrow*). **B**, Axial 0.7 mm gradient-echo T2-weighted image through the left inner ear. The enlarged endolymphatic duct contains normal fluid (*small white arrows*), while the normal fluid in the endolymphatic sac is replaced by soft tissues (*white arrowheads*). Normal fluid can be seen inside the posterior semicircular duct (*long white arrow*). The scala vestibuli/media (*double arrowhead*) is again larger than the scala vestibuli. **C**, Three-dimensional 3DFT-CISS reconstruction of the inner ear, viewed from above. The fluid-filled cochlea (*C*) and posterior semicircular duct (*double arrowhead*) can be seen. The triangular endolymphatic duct and sac are difficult to recognize because the normal fluid has been replaced by low signal intensity tissue (*white arrowheads*). Low signal intensity can be seen in the ampulla of the lateral semicircular duct (*small white arrows*) and in the posterior part of the vestibule (*long white arrow*).

group, the syndromes may share anomalies of the ear, neck, and shoulder, with the most common shared anomaly being fusion of two or more cervical vertebral bodies. In this group, inner ear anomalies are more common than outer or middle ear anomalies. In the otoskeletal group, the syndromes may share anomalies of the ear, face, and limbs, with the otic manifestations usually related to anomalies of osseous development, growth, or proliferation. Some syndromes fall into an ''other'' category, not having features common to other syndromes and not having a known cause or pattern of inheritance. A list of the more common or well-known syndromes can be found in Table 21-1, and Figures 21-66 to 21-71 show a few examples of the temporal bone findings on CT in some of these syndromes. The syndromes are listed alphabetically, and for many of them, note is made of one or more groups into which they may be classified or assigned. It must be emphasized that Table 21-1 represents only a partial list of syndromes that may involve the ear. There are many other textbooks dedicated to this subject alone.

- Ossiculoplasty and Ossicular Reconstruction
- Cochlear Implantation

INTRODUCTION

Infections of the temporal bone are usually considered based on anatomic regions: (1) the external ear, (2) middle ear and mastoid, (3) the inner ear, and (4) the petrous apex. The tissues and anatomic structure of each region have a strong influence on the types of infections occurring in that part of the temporal bone.

The external ear consists of the auricle and the external auditory canal. The external auditory canal is closed

medially by the tympanic membrane, thus isolating it from the middle ear, and the external canal is separated from the mastoid by a thick, bony wall lined by skin.

The middle ear contains the tympanic cavity that communicates with the nasopharynx via the eustachian tube. The tympanic cavity, its contents, and communicating air spaces, which include the air cells of the petrous apex, are completely covered with mucous membrane. Thus, infections and inflammations of the middle ear, mastoid, and petrous apex share some characteristics.

The inner ear consists of the membranous labyrinth enclosed in the osseous labyrinth, contained in the petrous bone.[1, 2]

Discussion of inflammation in the temporal bone will follow this anatomic organization. As infections of the middle ear are most often imaged, the discussion begins in that region, followed by the related petrous apex and then the inner and external ear. Much temporal bone surgery is done for infections of the ear, so postoperative findings are included in this chapter.

MIDDLE EAR AND MASTOID

Eustachian Tube Function

Understanding middle ear and mastoid disease requires knowledge of eustachian tube function. In addition, because all the pneumatized regions of the temporal bone are contiguous, inflammation of the middle ear may involve the other pneumatized spaces (mastoid, petrous apex, and perilabyrinthine air cells).[3–5] The formation of the mastoid antrum and mastoid air cells begins late in fetal life and continues during infancy and childhood.[1] The cavity and lining mucous membrane of the middle ear and eustachian tube arise from the expanding first pharyngeal pouch, and epithelium-lined projections emanating from the lining of the middle ear infiltrate the new bone.[1] Bone marrow is converted into a loose connective tissue stroma prior to pneumatization, and the pneumatized mastoid cavity develops after birth and grows to almost adult size by the age of 5 years.[6, 7] Primary pneumatization of the middle ear depends on numerous factors, including nutrition, heredity, and environment.[8–10] Aeration of existing cells is a dynamic process dependent on a normally functioning eustachian tube, and atticoantral aeration is further dependent on the patency of the anterior and posterior tympanic isthmi, which provide communication between the middle ear and attic.[11, 12] It is eustachian tube compromise (dysfunction or obstruction), with resultant decreased intratympanic pressure (ITP), that has been widely accepted as the primary cause of most of the subsequently discussed varieties of chronic inflammatory disease of the middle ear and mastoid (Table 22-1).[8, 13–16]

Middle ear infection in infancy and the inflammatory changes of the pneumatic space mucosa cause the subepithelial connective tissue to fibrose. Thus, growth of the pneumatic space is impaired and pneumatization is interrupted.[6, 17, 18] That is, recurrent tympanomastoid infections occurring in early childhood lead to arrest of mastoid pneumatization and result in a small mastoid cavity with sclerotic, bony walls. The additional presence of cholesteatoma may exacerbate the inflammatory response of middle ear infection and further suppress mastoid pneumatization.[19]

Table 22-1
COMPLICATIONS OF OTITIS MEDIA AND MASTOIDITIS

Extracranial
Intratemporal
Sequelae of Acute Otomastoiditis
Coalescent mastoiditis
Facial paralysis
SNHL (chemical toxins invade labyrinth via round window)
Labyrinthine fistula (usually result from cholesteatoma)
Labyrinthitis
Petrous apicitis
Sequelae of Chronic Otomastoiditis
Chronic otitis media with effusion
Tympanic membrane retraction
Tympanosclerosis
Acquired cholesteatoma
Granulation tissue
Cholesterol granuloma
Postinflammatory ossicular fixation
Noncholesteatomatous erosion of the ossicles (portion of the incus or stapes)
Conductive hearing loss
Osteoneogenesis
Extratemporal
Postauricular abscess
Bezold's abscess
Zygomatic abscess
Cervical/postauricular fistula
Extramastoid cholesteatoma
Intracranial
Epidural, subdural abscess
Cerebral abscess
Dural sinus thrombosis
Venous infarction
Otitic meningitis
Otitic hydrocephalus
Brain herniation

The eustachian tube (ET) connects the middle ear-mastoid complex with the nasopharynx. The ET has three functions with respect to the middle ear: (1) pressure regulation to equilibrate gas pressure in the middle ear with atmospheric pressure (this is a discontinuous process, as the middle ear is not constantly ventilated), (2) clearance of middle ear secretions into the nasopharynx, and (3) protection of the middle ear from nasopharyngeal secretions and sound pressure.[4]

The ET complex consists of a mucosal-lined lumen, a bony portion, a cartilaginous portion, and surrounding peritubal muscles (i.e., tensor veli palatini, levator veli palatini, salpingopharyngeus, and tensor tympani).[4] Overall, the ET is about 36 mm long and descends from the middle ear at an angle of about 45° with the midsagittal plane and 30° with the horizontal plane. The bony portion is about 12 mm long and is a tapered tube whose narrowest portion is near the pharynx. The cartilaginous portion of the ET is about 24 mm long and slightly flexible, being an incomplete tube along its lower and lateral margin, where it is completed by fibrous tissue. This configuration allows the opposing muscles attached to the cartilaginous portion of the ET immediately below the skull base to widen the tubal diameter and assist in maximizing the possibility of

Copyright © 2003, Mosby, Inc. All rights reserved.

equalizing pharyngeal and middle ear pressure. The narrowest portion of the entire ET system is at the bony-cartilaginous junction (isthmus), a location virtually inaccessible to therapeutic intervention.

Most anatomic and physiologic evidence supports the conclusion that cartilaginous tubal dilation is caused solely by the tensor veli palatini muscle, which originates along the lateral wall of the ET and the scaphoid fossa. This muscle converges to a tendon that wraps around the hamulus of the medial pterygoid muscle and inserts into the posterior border of the horizontal process of the palatine bone and the palatine aponeurosis of the anterior portion of the velum.

The bony ET (protympanum) lies within the petrous portion of the temporal bone and communicates with the anterior superior portion of the middle ear. The osseous portion normally remains open at all times. The fibrocartilaginous portion is closed at rest and opens during swallowing, yawning, sneezing, or a Valsalva maneuver. The ET opens for approximately 0.2 second once every 1 to 2 minutes, that is, for a total of 3 to 4 minutes every 24 hours.[7] There is an inherent tendency for gas to leave the middle ear by diffusion into the surrounding mucosa and circulation. This loss is compensated for by the ET admitting just enough air to maintain near-atmospheric pressure in the middle ear. If this system fails, negative pressure develops in the middle ear.[7]

Otitis Media and Mastoiditis

Otitis media is the second most common disease of childhood after upper respiratory tract infection. Two-thirds of children have at least one episode of otitis media by 3 years of age.[3] Acute otitis media with effusion (OME) is an infection of the middle ear, associated with pain and an effusion behind an intact tympanic membrane (Fig. 22-1).

Risk factors contributing to otitis media include low socioeconomic status and repeated exposure to many other children, either at home or in a day-care setting. Associated disease states include cleft palate, immunodeficiency, ciliary dyskinesia, trisomy 21, and cystic fibrosis. The protective effect of breast-feeding and the detrimental effect of secondhand smoke are significant in the first year of life.[20]

The middle ear, mastoid, and pneumatized petrous bone are extensions of the upper respiratory tract, and bacteria can enter the middle ear from reflux of infected secretions from the nasopharynx through the ET. Facilitating factors include bacterial colonization of the nasopharynx, incompetence of the protective function of the ET, and negative pressure in the middle ear relative to the nasopharynx.[21] Acute otitis media is often the sequel of a viral upper respiratory infection in which the mucosal barrier is disrupted, allowing adherence and growth of bacteria in the nose and nasopharynx. *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moxarella catarrhalis* are common pathogens.[20, 21]

The vast majority of patients with acute otomastoiditis are cured after a course of antibiotics, and no imaging is required.[8, 9] However, should computed tomography (CT) or magnetic resonance imaging (MRI) be performed at this time, nonspecific debris within the middle ear and mastoid is seen, possibly with several fluid levels (Fig. 22-2). Importantly, the integrity of the mastoid septae, ossicular chain, and external and internal mastoid cortices is preserved. As fluid may be found in the mastoids of asymptomatic individuals, the diagnosis of acute mastoiditis with air-fluid levels in the mastoid is a clinical diagnosis.

Acute otitis media may go on to a more chronic involvement of the middle ear and mastoid. Current terminology describes acute otitis media as the rapid onset of inflammatory signs and symptoms related to the middle ear. Fluid is usually seen behind the tympanic membrane. If fluid persists for 3 months, the disease is considered chronic.[3] Chronic

suppurative otitis media indicates that otorrhea has existed for at least 6 weeks. Otorrhea, defined as drainage from the ear, occurs through a nonintact tympanic membrane, either via placement of a tympanostomy tube or through a tympanic membrane (drum) perforation. A cholesteatoma may or may not be present.

Complications of Acute Otitis Media and Mastoiditis

Coalescent Mastoiditis

The clinical turning point for these patients occurs when mucoperiosteal disease extends into the bone. This results in the development of coalescent mastoiditis, defined as the erosion of mastoid septae with the associated development of an intramastoid empyema (Fig. 22-3, Table 22-1).[10, 22] As detection of subtle bony changes is required for diagnosis, high-resolution CT is the best imaging modality during this interval.[22] The radiologist must painstakingly seek subtle evidence of alteration of these mastoid septations, often comparing the affected side to the opposite side. Although some asymmetry between the two sides can occur normally (thereby potentially confusing the issue), usually the findings are not subtle and the diagnosis is obvious.

Importantly, in addition to the mastoid septae, the inner and outer mastoid cortices must be carefully studied. By direct extension, the mastoid disease may spread via a defect or thinning of the outer mastoid cortex to form a subperiosteal abscess that is generally postauricular in location (Macewen's triangle) (Figs. 22-4 and 22-5).[8] Perimastoid edema and cellulitis may occur, without a cortical defect, due to thrombosis of the mastoid emissary veins (Griesinger's sign) and spread of infection through foramina carrying emissary veins (Fig. 22-3).[23] Preauricular abscess formation is possible if the infection preferentially spreads along the zygomatic root. Necrosis of the mastoid tip (Fig. 22-6) allows infection to spread inferiorly into the neck deep to the fascial planes that surround the sternocleidomastoid and trapezius muscles. The result is a Bezold abscess. An untreated Bezold abscess can spread caudally to the larynx and mediastinum.[24, 25]

Facial Nerve Palsy

Facial nerve palsy is a rare complication of acute otitis media and is reported to occur in only about 5% of cases. Complete recovery is the rule.

Dural Sinus Thrombosis

Defects in the inner mastoid cortex, when present, place inflammatory debris in contact with the sigmoid sinus and adjacent dura (Figs. 22-7 and 22-8). The result may be dural thrombophlebitis and dural sinus thrombosis. Diagnosis is made by contrast-enhanced CT or MR and MR venography. A clot is seen as a filling defect within the dural sinus (''empty delta sign'') on contrast-enhanced CT or MR images obtained perpendicular to the dural sinus (Fig. 22-9).[26] Evaluation of the venous sinus on CT at appropriate window levels is crucial if one is to visualize a clot. MR is ideal for diagnosis and follow-up of dural venous sinus thrombosis.[27] The radiologist must scrutinize the images for the expected normal flow void in the venous sinuses on spin-echo sequences and flow-related enhancement on gradient-echo sequences. The absence of these normal venous signal intensities should arouse the suspicion of thrombosis. On occasion, signal characteristics allow for direct visualization of the clot within the lumen of the sinus (Fig. 22-9). Despite MR, the imaging diagnosis of dural

sinus thrombosis remains difficult because of the vagaries in flow phenomena and the varying signal intensity of blood products.[28] Thus, the hyperintense signal of normal flow-related enhancement may be confused with methemoglobin, and enhancement may occur in normal venous sinuses due to physiologic slow flow.[29] Artifactual flow gaps occur in about one-third of normal nondominant transverse sinuses because of signal loss secondary to in-plane vascular flow.[30] Subacute thrombus, composed of extracellular methemoglobin, may appear hypointense on T2-weighted images simulating a normal flow void. Subacute clot that is hyperintense on T1-weighted MR images due to methemoglobin may be confused with flow on time-of-flight MR venography, which utilizes T1-weighted gradient-echo techniques.[26] Organizing thrombus may enhance due to conversion of clot into vascularized connective tissue.[31]

VIEW IMAGE

FIGURE 22-6 Mastoiditis (coronal CT) with erosion of the medial mastoid tip (*arrow*). This defect could allow infection to spread inferiorly into the neck, causing a Bezold abscess.

Phase contrast or time-of-flight magnetic resonance angiography (MRA) may be done for the evaluation and follow-up of patients with suspected dural sinus thrombosis (Fig. 22-9).[31] An inferior presaturation pulse is applied to reduce the signal of arterial flow, and low-velocity encoding (VENC) gradients of 20 cm/sec should be collected.[29] The postcontrast 3D gradient-echo technique may offer the best sensitivity in the detection of abnormal dural venous sinus flow and thrombus.[32]

Identification of thrombus in the dural sinus is the definitive diagnostic imaging sign. However, caution must be used when evaluating magnetic resonance venographic studies. Firstly, the observer must be aware of variations in the size of the dural sinuses. Secondly, and more importantly, arachnoid granulations can appear as filling defects in the sinus and simulate clot on CT or MR, which may lead to a false-positive diagnosis of dural sinus thrombosis.[24, 33–37]

A CT scan with contrast and CT venography can also be used to evaluate the dural sinuses. Contrast is injected and a rapid scan done, catching the bolus passing through the vein. A thrombus is seen as a filling defect, and normal opacification of the vein is good evidence that the vein is patent. Organizing thrombus can enhance, but this is not considered a problem during the acute phase.

Dural sinus thrombophlebitis is preceded by epidural abscess in more than 50% of cases. Infected thrombus forms within the sinus and may break down to form an intrasinus abscess that is excluded from circulation by occlusive thrombi. Progression of infection and propagation of clot

may lead to thrombosis of the superior petrosal sinus and the cavernous sinus anteriorly and the jugular bulb and the internal jugular vein inferiorly. Meningitis and brain abscess may also occur and dominate the clinical picture, obscuring the signs of thrombophlebitis.

Venous Infarction

Thrombophlebitis of the sigmoid and transverse sinus may propagate retrograde into the superior sagittal sinus, causing venous outflow obstruction, and venous hypertension can lead to cerebral edema, infarction, and hemorrhage. Venous infarcts are characteristically subcortical (Fig. 22-9G) and do not conform to major arterial vascular territories. Infarctions due to superior sagittal sinus thrombosis are usually bilateral in the frontal, parietal, and occipital lobes. Infarctions of the thalamus occur with thrombosis of the internal cerebral veins and straight sinus. Transverse sinus thrombosis may result in temporal lobe infarction.[26]

Treatment is controversial. Some advocate endovascular approaches using direct infusion of thrombolytic drugs into the occluded sinuses to produce recanalization.[38, 39] Others promote ligation of the jugular vein to prevent dissemination of infected thrombotic material.[40–43]

Diffusion- and perfusion-weighted MR studies provide more information than conventional MR imaging about the

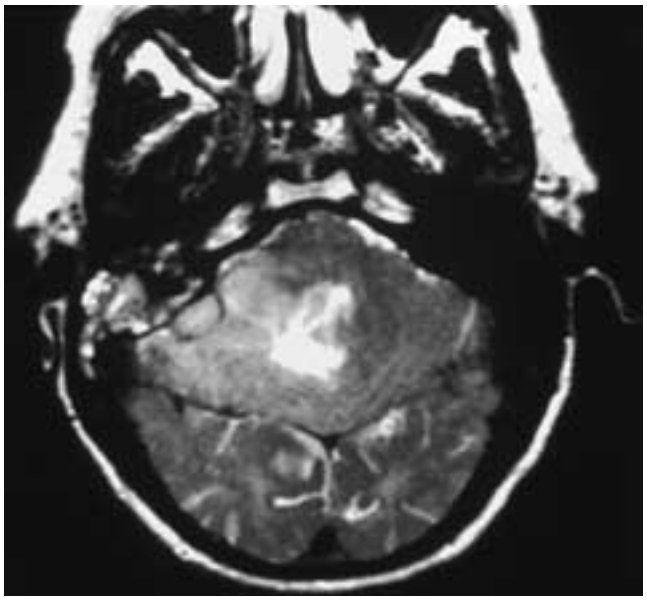
physiologic state of the brain after dural sinus thrombosis. These techniques may allow triage of patients between conservative therapy with heparin and microcatheter-directed thrombolysis.[44]

Abscess/Meningitis

Other dangerous intracranial complications include epidural, subdural, and intracerebral abscess formation (Figs. 22-8, 22-10, and 22-11). Meningitis and other intracranial inflammatory complications can occur via direct extension of disease from the mastoid through a cortical defect or can be secondary to retrograde thrombophlebitis, in which case the bone appears to be intact.[10] When a brain abscess develops, it usually occurs in the temporal lobe and cerebellum (2:1). Almost all otogenic brain abscesses have chronic suppurative otorrhea, and more than half have a cholesteatoma.[10]



VIEW IMAGE

FIGURE 22-11 Acute otomastoiditis with meningitis and ''cerebellitis.'' (Courtesy of Dr. David Yousem.)

Episodes of meningitis, particularly when they occur in children, should provoke a search for a parameningeal focus. When there is a history of otitis media, careful CT investigation of the margins of the temporal bone should ensue, with special attention to the tegmen, sinus plate, and lamina cribrosa. In this context, congenital fistulas, often associated with inner ear malformation, also must be sought.

Aberrant arachnoid granulations in the temporal bone should be sought for patients with persistent serous otitis media or septic meningitis following acute otitis media.[33] Anomalous arachnoid granulations appear as characteristic bone defects in the posterior or middle fossa surfaces of the temporal bone (Fig. 22-12), and the dural defect of an arachnoid granulation may permit intracranial extension of mastoid disease.

Otitic Hydrocephalus

Individuals with sigmoid sinus thrombosis are often gravely ill. Otitic hydrocephalus (otitic intracranial hypertension) is secondary to dural sinus thrombosis and is believed to result from impaired intracranial venous drainage. Further increased intracranial pressure may be caused by obstruction of arachnoid granulations along the

FIGURE 22-12 Anomalous arachnoid granulation. Note the defect in the mastoid cortex (*arrow*).

superior sagittal sinus, and alterations of posture can be catastrophic for those patients.[8–10] Changes in mentation and high spiking fevers (''picket fence'' fever pattern) are among the classic clinical findings associated with this disorder. Mastoid exploration with surgical decompression of the adjacent dural sinuses is often curative.[10, 26]

Labyrinthitis

Labyrinthitis is also a potential complication of acute otomastoiditis, and access to the labyrinth is usually via the round or oval window.[8–10] Exotoxins also have been implicated in the development of labyrinthitis, suggesting hematogenous dissemination. Imaging reveals pathologic contrast enhancement within the membranous labyrinth on T1-weighted, contrast-enhanced studies. This phenomenon will be considered again in the section on the inner ear.

FIGURE 22-13 Chronic otitis media with effusion. Otoscopy.

Chronic Otitis Media with Effusion

Chronic otitis media with effusion (COME) is an accumulation of inflammatory effusion in the middle ear and a frequent sequela of acute otitis media.[21] Otitis media with effusion is also known as *serous otitis* (Fig. 22-13). Middle ear effusion results from decreased intratympanic pressure and may occur as an isolated phenomenon or in association with other manifestations of chronic otitis media.[14, 16, 45] Serous otitis media is associated with malfunction or obstruction of the ET. The etiology includes abnormal development of the temporal bone and obstruction of the ET by bone dysplasia, trauma, adenoid hyperplasia, tumor, or surgery. Tubal patency may be compromised by mucosal edema secondary to rhinopharyngitis, allergy, or neoplasm.[46]

Occlusion of the ET causes a decrease in intratympanic pressure and impaired air exchange in the middle ear. Negative intratympanic pressure results from resorption of oxygen by the mucoperiosteum of the middle ear, and the negative pressure causes collapse of the tubal wall and occlusion of the tubal isthmus. There is then extravasation of fluid from the vascular bed into the intercellular spaces and air spaces of the middle ear.[46]

Persistent ET dysfunction may lead to a succession of events. There may be atrophy of the drum, with or without attic retraction pockets. There is greater risk of tympanic membrane (TM) perforation due to trauma or acute otitis. Poor TM healing results in an increased chance of perforation.[5] Long-standing ET dysfunction may result in middle ear atelectasis. The TM becomes retracted onto the promontory and ossicles of the middle ear (Figs. 22-14 and 22-15).[47] These retractions may be associated with ossicular defects (long process of incus) and, when exaggerated, may result in an ossicular discontinuity whereby the TM is placed in direct apposition to the stapes capitulum (''nature's

myringostapediopexy'') (Fig. 22-15). These patients often have normal conductive hearing.[10, 45]

Osteoneogenesis may be caused by chronic healed otitis media and mastoiditis. Osteoneogenesis is unusual in the middle ear but is a common sequela to infection in other pneumatized areas of the temporal bone. The thickened bony trabeculae coalesce and progressively obliterate the intervening air spaces.[10]

Middle ear effusions occurring in infants and children are usually treated without the aid of radiologic intervention.[16] However, middle ear effusions occurring spontaneously in an adult should be investigated with imaging and should include examination of the nasopharynx to exclude a neoplasm obstructing the ET (Fig. 22-16). Nasopharyngeal imaging should be performed routinely at the time of temporal bone examination.

Another cause of middle ear effusion is trigeminal motor dysfunction. The mandibular branch of the trigeminal nerve provides innervation to the tensor veli palatini muscle, which regulates ET patency. Tensor veli palatini dysfunction secondary to V3 denervation will compromise ET function and cause middle ear and mastoid fluid to accumulate. The etiology is usually a tumor in the cavernous sinus region or perineural spread of malignancy.[48]

Effusions may occur anywhere in the middle ear cleft (tympanic cavity proper) or within the attic, antrum, or mastoid air cell system. The imaging diagnosis is made by demonstration of an air-fluid level, preferably in two orthogonal planes.[45] Unfortunately, the diagnosis of an effusion in the completely opacified middle ear often is not possible because no fluid levels are seen, and CT attenuation numbers are unreliable because of the diversity of the components of the collection. Tympanostomy tubes (pressure-equalization tubes) are used in these patients both for drainage and for normalization of intratympanic pressure (Fig. 22-17).[14, 49, 50] These tubes are made of various plastics and metals, including stainless steel. They are of widely varying shapes and are consistently visible at CT, except when obscured by adjacent soft-tissue debris.[51–53] Ventilation tubes tend to be spontaneously extruded from the TM after 3 to 6 months.

Sequelae of Chronic Otitis

Granulation Tissue

Granulation tissue is probably the most common cause of debris in the middle ear. On CT, a soft-tissue density is seen, with no ossicular displacement or bone erosion. The distinction between granulation tissue and cholesteatoma can be made with contrast-enhanced MR imaging. Granulation tissue is usually quite vascular and enhances intensely on contrast-enhanced, T1-weighted images, while cholesteatoma does not enhance (Fig. 22-18).[11, 23, 24, 54] Hearing loss and aural drainage are variable findings with granulation tissue, and one must be aware that such granulation tissue often occurs concurrently with other manifestations of chronic otitis, including cholesteatoma.[11, 45, 53, 55, 56]

Cholesteatoma

A cholesteatoma is simply skin growing in the wrong place and consists of a sac lined with stratified squamous epithelium filled with exfoliated keratin debris. A cholesteatoma may be classified as either acquired or congenital in origin.[10, 15, 24, 56, 57] An acquired middle ear cholesteatoma is the most common type (98%) and occurs in the context of chronic otitis media and/or a perforated TM.[24, 58] This type of cholesteatoma has also been called a secondary-acquired cholesteatoma, a Prussak's cholesteatoma, or an attic cholesteatoma. Cholesteatomas arising from retraction pockets in the absence of infection are known as primary acquired cholesteatomas and may be the result of extension of squamous epithelium from the pars flaccida into the unresolved mesenchyme of the epitympanum in early life[59] (Table 22-2).

Congenital (primary) cholesteatomas of the temporal bone are due to epithelial rests of embryonal origin. Congenital cholesteatomas (epidermoids) within the tempo-

VIEW IMAGE

ral bone have been reported in the middle ear, mastoid, middle ear and mastoid, petrous portion of the temporal bone, temporal squama, and within the TM. Intradural (cisternal) congenital cholesteatoma is another type of cholesteatoma that usually involves the cerebellopontine angle (CPA) and may cause varying degrees of cochlear and vestibular symptoms and signs.[58, 60, 61] A cholesteatoma in the diploic space is in the differential diagnosis of a solitary lytic calvarial lesion. Although congenital cholesteatomas of the middle ear may occur anywhere, they tend to occur in the anterior tympanic cavity near the ET or stapes.[23]

The acquired cholesteatoma is unique to the middle ear, and its etiology is related to the anatomy and embryology of the TM.[15, 62] The TM contains all three germinal layers; an external epidermal layer contiguous with the skin (ectoderm), an inner layer continuous with the mucosa of the middle ear (endoderm), and a middle fibrous layer (mesoderm). The skin on the outer surface of the TM grows quite rapidly, desquamates, and then normally migrates outward from the external auditory canal with cerumen, which develops in the lateral cartilaginous third of the external auditory canal.[15, 63]

Most acquired cholesteatomas arise in the superior pars flaccida portion of the TM and extend into Prussak's space (Fig. 22-19). Prussak's space is limited laterally by the pars flaccida (Shrapnell's membrane), which is attached superiorly to the tympanic ring near the scutum, inferiorly by the lateral (short) process of the malleus, and medially by the neck of the malleus. The superior and anterior walls are formed by the lateral mallear ligament, which radiates from its site of origin on the neck of the malleus to the scutum and from the anterior and posterior malleal folds.[10, 12, 23, 64–66]

There are four major theories concerning the etiology of acquired cholesteatoma (Table 22-3). Perhaps the most widely accepted theory suggests that cholesteatoma arises from retraction pockets (Figs. 22-20 to 22-22). If negative pressure develops in the middle ear, atmospheric pressure compresses the TM from the outside, causing the weakest portion to retract. Thus, the pars flaccida, lacking a well-defined middle fibrous layer, retracts more easily due to its elasticity.[7, 67] Healing perforations of the pars tensa may also be predisposed to retract. As the retraction pocket forms and deepens, due to negative middle ear pressure and possibly repeated inflammation, the TM retraction pocket disrupts the normal physiologic desquamation of the external epidermal layer of the TM. This allows debris to become trapped within the pocket, accumulate, expand, and form a keratin plug.[47, 68–70] A cholesteatoma is formed.

Table 22-2
CLASSIFICATION OF MIDDLE EAR CHOLESTEATOMA

Congenital cholesteatoma	2%
Acquired cholesteatoma	98%

Other etiologies of secondary acquired cholesteatoma include epithelial invasion or implantation of skin into the middle ear through a perforation in the TM secondary to otitis media, surgery with placement of ventilating tubes, or tympanoplasty.

Other pathogenic theories involve metaplasia of the simple squamous or cuboidal epithelium of the middle ear into keratinized stratified squamous epithelium secondary to chronic or recurrent otitis media. Proponents of basal cell hyperplasia theorize that epithelial cells, via proliferating columns of cells, invade the intact TM through microscopic defects.[47] Such epithelial migration is facilitated by infection that destroys the normal middle ear mucosa.[68, 70] Epithelial breaks are also commonly observed in the middle ear in association with otitis media. These dehiscenses leave areas of connective tissue from the mucoperiosteum in direct contact with a middle ear effusion. As the effusion becomes organized, it serves as a bridge for granulation tissue. In later stages, these areas become totally or partially covered with epithelium, and these epithelial breaks become connected to each other through the organized effusion. The cholesteatomas seem to spread by using the connective tissue as scaffolding.[71] Because the TM appears to be normal, these cholesteatomas are impossible to differentiate from the congenital type.

By virtue of their location in Prussak's space, acquired cholesteatomas generally displace the malleus head (and incus body) medially and erode the adjacent bony scutum (junction of the lateral attic wall and external auditory canal at the lateral attic spur) (Figs. 22-23 and 22-24).[56, 66, 72, 73] Prussak's space opens posteriorly into the epitympanum. From there, the mass easily extends posteriorly in the superior incudal space to the posterolateral attic and then via the aditus ad antrum to the antrum and mastoid air cells. Widening of the aditus is often an important imaging diagnostic finding.[74] Larger lesions may extend from the attic inferiorly into the posterior tympanic recesses.

Cholesteatomas arising from the pars tensa are much less common than those arising from the pars flaccida. Most pars tensa cholesteatomas arise from posterosuperior retractions and often involve the recesses of the posterior tympanum, initially the facial recess laterally and then the more medial sinus tympani (Fig. 22-25).[62] Superior extension of these lesions into the attic generally displace the ossicular mass (malleus head and incus body) laterally. Thus, the pars tensa cholesteatoma tends to extend initially toward the medial wall of the middle ear and comes into contact early with the ottic capsule over the lateral semicircular canal. As a result, fistulous formation to the lateral semicircular canal is more commonly seen than in the pars flaccida cholesteatoma. The pars tensa cholesteatoma is easiest to diagnose on axial CT, in contrast to the early Prussak's-type cholesteatoma, which is best seen on coronal images.

Middle ear opacification, associated with TM retraction, is a helpful diagnostic clue that indicates the absence of a mass lesion (cholesteatoma, paraganglioma, etc.) in the middle ear.

The most medial extension of the anterior epitympanic space is known as the anterior epitympanic recess or supratubal recess. The supratubal recess is separated from the main epitympanic space by an incomplete bony or fibrous partition attached to the tegmen anterior to the malleus. This bony ridge has been named the *cog* by Dr. William House (Fig. 22-26A). This recess is in intimate contact with the proximal tympanic segment of the facial nerve and the geniculate ganglion. If the cog is absent, cholesteatomatous masses may spread anteriorly and jeopardize the facial nerve in the region of the geniculate ganglion (Fig. 22-26B,C).[75] Other conditions leading to the development of an anterior epitympanic cholesteatoma are a canal wall down mastoidectomy or blockage of the aditus ad antrum.[75]

The imaging signature of cholesteatoma is bone erosion associated with a nonenhancing soft-tissue mass, and it is the bone destruction that makes these lesions particularly dangerous[57] (Table 22-4). Cholesteatomas may erode the scutum, ossicles, tegmen tympani, and bony labyrinth.

Erosion of the scutum is the classic finding in attic cholesteatoma.[23] Ossicular destruction occurs in 75% of pars flaccida cholesteatomas and in as many as 90% of pars tensa cholesteatomas.[76–79] The long process of the incus, by virtue of its limited ligamentous support and poor blood supply, is the most common segment of the ossicular

chain eroded by both varieties of acquired cholesteatoma. The stapes also must be carefully evaluated when the lesion involves the oval window niche. Amputation of the malleus head and incus body occurs classically in far-advanced lesions, particularly those arising in Prussak's space (Fig. 22-27).

Labyrinthine fistula is a potentially serious complication of cholesteatoma, with an incidence of 5% to 10%. In order of decreasing frequency, fistulas occur in the lateral semicircular canal, superior ampulla, posterior canal, and promontory of the cochlea.[10] By far the most commonly compromised region is the lateral semicircular canal (Fig. 22-28). In all patients with middle ear disease, this area should be carefully evaluated on both coronal and axial images for evidence of cortical thinning. The diagnosis of fistula can be made when the mass is in direct apposition to the lumen of the labyrinth. The patient usually has symptoms of vertigo intermittently complicating long-standing chronic otitis. Classically, the patient has an acute vertiginous episode during otoscopic manipulation of the lesion. Identification of bony erosion in the absence of a gross fistula is also important to note because surgical removal of the adjacent mass may cause an acute fistula. Complications of fistula formation include the potential for total hearing loss and persistent, unremitting vertigo.[63] The latter complication may necessitate labyrinthectomy.

The facial nerve canal can be eroded; thus, it must be carefully evaluated on imaging.[80] Even if there is erosion, however, facial nerve function may be normal. Facial nerve dysfunction occurs in approximately 1% of patients with cholesteatoma.[23] The most common site of facial nerve compression is the tympanic segment, which lies inferior to the lateral semicircular canal in the middle ear. When a complete bony canal is present, erosion of the canal wall is easily seen on imaging (Fig. 22-29B). Unfortunately, the tympanic facial nerve segment may be covered by a very thin layer of bone or may be an uncovered canal with the nerve exposed to the middle ear. In such cases, subtle erosion is difficult, if not impossible, to demonstrate. However, gross invasion of the facial nerve canal in these regions is quite demonstrable.[53, 56, 81]

Bony erosion may also occur at several other strategic locations. Especially ominous is involvement of the tegmen tympani and sigmoid sinus plate (Fig. 22-29). MR imaging is recommended when defects occur at these sites because there could be associated epidural invasion by cholesteatoma, increasing the potential for development of meningitis, cerebritis, or abscess should the lesion become infected. MR imaging also is useful to define an encephalocele extending through the eroded tegmen (Fig. 22-30).

The precise etiology of the bone destruction that occurs secondary to cholesteatoma has not been identified. However, there has been excellent documentation that stratified squamous epithelium, in the absence of associated granulation tissue, does not erode bone.[15, 76, 77, 82]

Simple mechanical pressure is a doubtful cause because it is unlikely that a cholesteatoma could exert pressure exceeding capillary perfusion pressure (approximately 25 mm Hg). Chole and Choo have shown that bone resorption is primarily caused by multinucleated osteoclasts that activate or produce enzymes such as acid phosphatase, collagenase, and acid proteases.[47]

Cholesteatomas provide an excellent culture medium, and there is always potential for infection. In the preantibiotic era, such infection was responsible for most life-threatening intracranial complications such as meningitis, abscess, and sinovenous thrombosis. Fortunately, today these complications are rare.[56, 82–85] Individuals with clinical evidence of one of these intracranial complications should probably undergo MR imaging before CT.

The differential diagnosis of a destructive middle ear mass includes cholesteatoma, rhabdomyosarcoma, Langerhan's cell histiocytosis, squamous cell carcinoma, metastasis, giant cell tumor, and xanthoma.

The CT density of middle ear debris is not histologically specific.[86] The observer must rely on secondary factors to arrive at an appropriate diagnosis. Such factors include age, location, distribution, calcification or ossification, TM status (bulge or retraction), bony erosion, degree of mastoid pneumatization, and amount of conductive hearing deficit. Bony alteration is commonly associated with attic cholesteatoma, and this diagnosis should be questioned if such changes are not present. Typical findings associated with cholesteatoma include scutum blunting, attic expansion (lateral wall remodeling), and erosion of the anterior tympanic spine. The latter structure (inferior border of the Glaserian fissure) is best appreciated in the sagittal plane.[87]

Holotympanic debris in the absence of TM alteration or significant conductive hearing deficit quite likely represents granulation tissue or fluid.[88] In the presence of TM retraction and conductive deficit, the possibility of inflammatory ossicular fixation should be considered, especially when there is associated calcification or ossification. It should be remembered that granulation tissue may accompany cholesteatoma. Contrast-enhanced, T1-weighted MR images are highly accurate in separating typical granulation tissue, which enhances, from cholesteatoma, which does not (Fig. 22-31). The MR signal (nonenhanced) characteristics of cholesteatomas of the middle ear are nonspecific, and ordinarily both T1 and T2 relaxation times are relatively long.[89, 90] If bone destruction is excessive, neoplasm must be considered (Fig. 22-28C). Such neoplasms, fortunately, are quite unusual and often are accompanied by sclerosis and bloody discharge.[91] When these lesions are large, the exact site of origin may be difficult to discern. In children, rhabdomyosarcoma is notorious for its propensity to masquerade as benign middle ear disease.[92]

A cholesteatoma can evacuate spontaneously through the external canal, leaving a cavity that has an appearance similar to that of a mastoidectomy. The resulting defect is called an automastoidectomy (Fig. 22-32) and is discussed later in this chapter.

Ossicular Erosions and Ossicular Fixation

The high incidence of conductive hearing deficit (CHD) in individuals with congenital and acquired cholesteatoma is well known, and ossicular erosions are the predominant cause. Less well described is the commonplace occurrence of CHD due to ossicular resorption as a complication of chronic otitis media (Fig. 22-33), or ossicular fixation. These patients could possibly have a healed TM, and fenestral otosclerosis may be suspected clinically.

VIEW IMAGE

FIGURE 22-31 Cholesteatoma—granulation tissue. **A** and **B**, Axial and coronal contrast-enhanced, T1-weighted image demonstrates enhancing granulation tissue (*arrows*) surrounding a nonenhancing cholesteatoma.

Erosive changes occur, in order of decreasing frequency, in the long process incus, crura of stapes, body of the incus, and manubrium.[77] Attic changes (malleus head or incus body) are less common but occur on occasion (Fig. 22-34). Both axial and coronal images must be carefully studied to make a specific anatomic diagnosis.[93] The coronal images yield the best information regarding the status of the vertically oriented long process. The remainder of the chain is best visualized on axial CT scans; on images obtained just inferior to the oval window, two parallel ''lines'' representing the stapes crura should be seen.[53, 93] Anteriorly, the tensor tympani tendon and malleus neck are identified, and more posteriorly and more importantly, the lenticular process of the incus and the stapes superstructure are identified with the intervening incudostapedial joint (ISJ) (Fig. 22-35). This region should be carefully scrutinized because a widened ISJ could be secondary to erosive changes and is associated with fibrous replacement.[94] Ossicular defects are seen to best advantage in the nonopaque ''dry ear.''

Ossicular fixation also may be responsible for postinflammatory CHD.[95–98] At CT, fibrous tissue has a nonspecific appearance (Fig. 22-36). The observer should be alerted to this diagnosis in the presence of nonerosive and

nonexpansile changes in the middle ear of a patient with a wide audiometric air-bone gap (CHD). The TM is often retracted. The fibrous tissue may be generalized or focal. If it is focal, there is a propensity for involvement in the region of the oval window (peristapedial tent) and Prussak's space.

Tympanosclerosis

Tympanosclerosis (or dystrophic calcification) is caused by chronic otitis media followed by healing. The result is fibroblastic invasion of the submucosa, with resultant thickening and fusion of collagenous fibers to form a homogeneous mass in the tympanic cavity, with deposition of intra- and extracellular calcium and phosphate crystals.[10, 95, 99–101]

Involvement of the TM is common but often is asymptomatic (Fig. 22-37). CHD results when the process involves or encases the ossicles or their suspensory ligaments and tendons.[102] The CT appearance consists of punctate or web-like calcific density(s) (Fig. 22-38). Peristapedial tympanosclerosis may be treated with prosthetic stapedectomy, a procedure with an increased incidence of poor results in this clinical setting.[103]

New bone formation (fibroosseous sclerosis) is the least common histologic type of postinflammatory ossicular fixation.[95] This is most likely to occur in the attic and to cause encasement of the ossicular chain (Fig. 22-39).[102]

Miscellaneous

Tuberculosis

The incidence of tuberculosis and the number of drug-resistant strains of *Mycobacterium tuberculosis* have been increasing with the rise of HIV-infected patients. *M. tuberculosis* can involve multiple head and neck sites, including the larynx, pharynx, oral cavity, nasal cavity, salivary glands, cervical spine, middle ear, and mastoid. The eighth cranial nerve is very frequently affected. Tuberculous otitis media and mastoiditis have an insidious painless onset and a chronic course[23] (Fig. 22-8). TM involvement leads to early perforation and aural discharge, allowing release of the purulent exudate before there is sufficient accumulation of pus to cause pain. The portal of entry of tuberculous otitis media may be the ET or hematogenous spread of a casseous focus.

Mycotic Infections

Mycotic infections are more common in immunocompromised hosts, diabetics, and patients with lymphoma or burns. Candidiasis, aspergillosis, phycomyosis (mucormycosis), noncardiosis, and cryptococcosis are typical examples of these opportunistic infections.

PETROUS APEX

Abnormalities of Aeration of the Petrous Apex

The petrous apex may be pneumatized (filled with mucosa-lined air cells) (33%), filled with marrow (60%), or sclerotic (7%).[104–106] Air cells extend into the petrous apex from the middle ear following tracts above and below the cochlea.[107, 108] Pneumatization is asymmetrical in 4–7%.[105, 106] Because the petrous apex contains mucosa-lined air cells, middle ear infection can lead to obstruction and inflammation of these apex cells and a spectrum of clinical problems, including effusion, apicitis, mucocele, and cholesterol granuloma.

Petrous Apex Effusion

Simple effusion is often an incidental finding and probably the most common radiographically identified abnormality of the petrous apex.[109] Fluid in the petrous apex usually has a bright signal on T2-weighted images but can have variable signal intensity, depending on the protein content. However, CT is necessary for definitive evaluation of these cells to exclude expansion and destruction and to define intact intercellular bone septations (Fig. 22-40).[105, 108]

Acute Petrositis

Apical petrositis is caused by spread of infection from the middle ear to the pneumatized areas of perilabyrinthine and apical regions of the temporal bone. Petrous apicitis has been considered synonymous with the complex of symptoms described by Guiseppi Gradenigo in 1904. Gradenigo's syndrome results from a suppurative otitis media that spreads to the petrous apex and then extends further to affect adjacent intracranial structures. The syndrome includes a middle ear infection with otorrhea, pain in the orbit or behind the eye (trigeminal ganglionitis), and lateral rectus palsy secondary to involvement of the sixth nerve as it follows Dorello's canal across the tip of the petrous apex.[110, 111]

The classic Gradenigo triad is rarely present, and cranial nerves II, III, VII, VIII, IX, and X may also be involved.[11, 22, 112, 113] Petrous apicitis should be suspected whenever a chronic suppurative ear infection is associated with deep ipsilateral pain.[111]

The pathogenesis of petrous apicitis is assumed to be extension of infection from the middle ear and mastoid air cells into the pneumatized petrous apex via the perilabyrinthine air tracts. The trigeminal ganglion is affected in Meckel's cave, located on the petrous apex. Meckel's cave

lies near Dorello's canal. The abducens nerve exits the pontomedullary junction, ascends in the subarachnoid space, and pierces the dura on the back of the clivus to enter a petroclival venous confluence located between two layers of dura. This petroclival venous confluence contains the inferior petrosal sinus, which drains into the jugular bulb. The petroclival venous confluence communicates with the cavernous sinus anterosuperiorly, the superior petrosal sinus laterally, and the basal sinus of the clivus medially. At the level of the petrous apex, the sixth nerve penetrates an osteofibrous conduit (Dorello's canal) that is formed by the petrous apex and the petrosphenoidal ligament (Gruber's ligament). The sixth nerve then enters the cavernous sinus and runs along the lateral aspect of the internal carotid artery.[114–116]

Whether petrous apicitis always occurs in a pneumatized petrous apex is a matter of dispute. Petrositis has been described in the nonpneumatized apex presumably due to hematogenous spread of infection. Suppuration in the petrous apex may be a true osteomyelitis of the medullary bone of the petrous apex or the result of coalescent osteitis within the pneumatized spaces of the petrous apex.[111, 117] Most researchers consider the development of petrous apicitis to be a complication of acute purulent otitis media, paralleling the occurrence of coalescent mastoiditis as a complication of acute otitis media.

CT scans reveal debris within petrous apex air cells. Lysis of bony septae and disruption of the adjacent bony cortex may also occur. Occasionally, petrositis presents only with fluid in the petrous apex, without bone destruction. The MR findings include pathologic enhancement at the periphery of the defect, presumably within meninges, with possible extension to the gasserian ganglion (Meckel's cave) (Figs. 22-41 and 22-42).

VIEW IMAGE

FIGURE 22-43 Petrous apicitis with intracranial abscess. **A**, Coronal CT image shows opacification of the left petrous apex with cortical erosion (*arrow*). **B**, T1-weighted, contrast-enhanced MR image reveals enhancement of the petrous apex and an adjacent temporal lobe abscess.

Complications of petrositis include meningitis, epidural abscess, brain abscess, and venous sinus thrombosis (Fig. 22-43). The sigmoid sinus, cavernous sinus, and jugular vein are at risk because of their proximity to the petrous apex.[108]

Cholesterol Granuloma, Mucocele, and Cholesteatoma

The three most common expansile lesions to arise within the petrous apex are the cholesterol granuloma (cholesterol cyst), the cholesteatoma, and the rare mucocele. The cholesterol granuloma is six times more common than the cholesteatoma.[118, 119]

Mucoceles of the petrous apex and paranasal sinus have a similar pathophysiology. Obstruction of air cells occurs while there is continued mucosal secretion of mucus. As a result, the involved sinus, or air cells, become remodeled and expanded. This is an unusual lesion of the petrous apex, probably because there are so few mucous glands.

Cholesterol granuloma (CG) (or cholesterol cyst) is an expansile, erosive lesion that occurs in the middle ear, mastoid, or petrous apex.[10] It develops as a result of obstruction that leads to a repetitive cycle of hemorrhage and granulation tissue formation.[120]

Patients with CG often have a history of purulent or serous otitis media and allergies, and there is impairment of ventilation in the petrous air cells. CG is a foreign body giant cell reaction to cholesterol deposits that occur in obstructed, fluid-filled air cells in the temporal bone. Microscopically, the CG contains numerous clefts of cholesterol crystals surrounded by histiocytes, round cells, macrophages, and many small, often pathologic blood vessels. These fragile blood vessels are prone to rupture, producing contiguous areas of new and old hemorrhage.[10, 46] CG can be thought of as a hemorrhagic mucocele. CGs are lined by fibrous connective tissue and not keratinized stratified squamous epithelium, as are cholesteatomas.[121]

It is believed that the obstruction of the petrous air cells leads to negative intraluminal pressure, which in turn causes rupture of the fragile vessels that line the air cells. The resulting hemorrhage and blood products, and the reaction to them, are the pathophysiologic basis of the CG.

CG occurring within a mastoidectomy cavity has been variously referred to as a chocolate cyst or a blue-domed cyst. If the TM has healed and a history of chronic otitis media is not elicited, otoscopically a CG in the middle ear may mimic a vascular mass such as an aberrant internal carotid artery, an exposed dehiscent jugular bulb, or a paraganglioma.[46, 122] The CT appearance is that of a nonspecific soft-tissue density. The MR appearance of high signal intensity on all sequences, secondary to the presence of extracellular methemoglobin, is diagnostic (Fig. 22-44).[123, 124] Frequently, there are areas of low signal as well, representing hemosiderin.

Petrous apex effusions with high T1 signal intensity may be confused with CG. CT is necessary to demonstrate the nonexpansile air cell opacification with intact bone septation.

Cholesteatoma of the petrous apex may be primary, arising from epithelial rests, or acquired.[119] The histologic findings are identical, and most of these lesions are primary in etiology.[108]

On occasion, aggressive middle ear cholesteatomas can spread from the middle ear into the pneumatized petrous apex. They do so by detouring around the bony labyrinth, following pathways of least resistance: infralabyrinthine, anterosuperior, and posterosuperior air tracts (Fig. 22-45).[89,124] They may also expand and extend along the facial nerve canal.[108]

VIEW IMAGE

FIGURE 22-44 Cholesterol granuloma. **A**, Coronal T1-weighted image without contrast shows the high signal expansile lesion in the petrous apex. An area of low signal (*arrowhead*) within the abnormality is believed to represent hemosiderin. **B**, Axial T2-weighted image shows the high signal of the cholesterol cyst. Again, the low signal (*arrowhead*) represented hemosiderin.

On CT, a cholesteatoma is a smooth-walled, expansile lesion with a density slightly lower than that of brain. On MR, the lesion has a similar signal intensity to brain (low to intermediate signal intensity on T1-weighted images and higher signal intensity on T2-weighted images). This pattern distinguishes cholesteatoma from CG, which is bright on both T1- and T2-weighted images.[108] The differential diagnosis of a smooth-walled, expansile lesion of the petrous apex includes a petrous carotid aneurysm and a meningocele (Fig. 22-46). Apex meningoceles are seen as fluid-filled cavities in the petrous apex. There may be slight expansion. On CT a meningocele can mimic a cholesterol

VIEW IMAGE

granuloma but with MR imaging signal follows CSF exactly. T1-weighted images show low signal rather than the high signal characteristic of a cholesterol granuloma or cyst. These meningoceles often connect to Meckel's cave and will fill with contrast injected intrathecally.

INNER EAR

Labyrinthitis

Labyrinthitis implies an inflammatory process involving the membranous labyrinth.[10, 125–127] The labyrinth may be involved as part of a systemic disease or as the primary target of an invading agent.[128] Labyrinthitis may be classified according to its etiology as viral, bacterial, luetic, posttraumatic, or autoimmune[129, 130] (Table 22-5). Another classification is based on the portal of entry of the offending agent and subdivides labyrinthitis into tympanogenic, meningogenic, hematogenic, and posttraumatic categories.[10] Labyrinthitis is most commonly the result of a viral infection.[23, 109]

Bacterial Labyrinthitis

Bacterial labyrinthitis is an unusual complication of acute infection of the middle ear (tympanogenic labyrinthitis). The labyrinth connects with the middle ear via the oval and round windows, and breaching of the round window membrane is often implicated as the course of spread of middle ear infections. Labyrinthitis also may occur secondary to a labyrinthine fistula, which most commonly occurs at the level of the lateral semicircular canal and is usually the result of a cholesteatoma. Most often, labyrinth involvement is a reaction to bacterial endotoxins rather than bacterial invasion.

Bacteria may reach the cochlea from the subarachnoid space (meningogenic labyrinthitis), and meningogenic labyrinthitis is often bilateral.[10] Bacterial labyrinthitis with profound hearing deficit occurs in about 10% of patients with bacterial meningitis. Vestibular neuritis, producing intense vertigo, is commonly thought to also have an infectious origin.[131]

Medially the labyrinth potentially communicates with the CSF spaces via the cochlear aqueduct and the IAC. The cochlear aqueduct arises in the basal turn of the scala tympani near the round window, and ends caudal to the porus acousticus and medial and cranial to the jugular fossa.[128] Bacterial meningitis invasion is believed to occur via either the cochlear aqueduct or the small perforations in the fundus of the IAC (lamina cribrosa) that transmit the cranial nerves. Pathogens include *Haemophilus influenzae*, *Neisseria menigitidis*, *Streptococcus pnemonniae*, *Escherichia coli*, *Proteus*, *Listeria moncytogenes*, and *M. tuberculosis*.[128] Ototoxic antibiotics used to manage infection may also contribute to auditory and vestibular symptoms.

Infectious processes also can be transmitted to the membranous labyrinth via a hematogenous route through the cochlear vasculature. This is referred to as hematogenous labyrinthitis.[10] These cases are usually viral in nature, and mumps and measles often have been implicated. Syphilis, tuberculosis, and other bacterial infections also can cause hematogenic labyrinthitis.

Posttraumatic labyrinthitis occurs in the context of previous injury, especially when a fracture is present. Iatrogenic tympanogenic labyrinthitis can occur after middle ear surgery. Clinically, there is sensorineural hearing loss and vertigo.

Regardless of the etiology, the MR imaging finding in labyrinthitis is contrast enhancement of the normally nonenhancing, fluid-filled spaces of the labyrinth[23, 24, 125, 132] (Fig. 22-47). There also is an excellent correlation between such enhancement and the presence of clinical symptoms.[132]

A precontrast T1-weighted image should be obtained because of the importance of distinguishing enhancement of labyrinthitis from intralabyrinthine hemorrhage. In cases of hemorrhage, the normal low labyrinthine T1-weighted signal intensity is replaced by a high signal intensity due to the presence of methemoglobin.[133] Such hemorrhage may be due to labyrinthitis but more commonly results from coagulopathy, neoplasm, or trauma. Intralabyrinthine hemorrhage is also associated with barotrauma, sickle cell disease, and tumor fistulization.[134, 135] T1 shortening may also be produced by proteinaceous fluid.

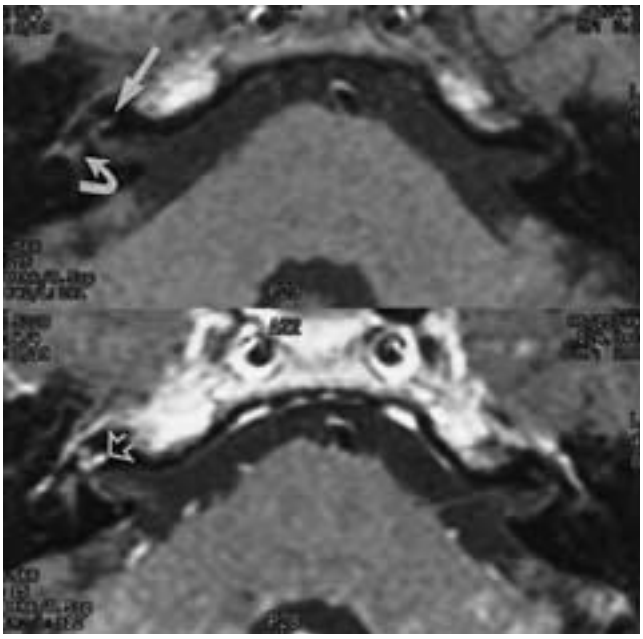

FIGURE 22-47 Labyrinthitis. T1-weighted images before (top) and after (bottom) gadolinium enhancement. Four weeks after trauma, this 21-year-old man had persistent hearing loss in the right ear. Note the mild hyperintensity of the right cochlea (*arrow*) and vestibule (*curved arrow*) on the unenhanced image. There is marked contrast enhancement of the cochlea (*open arrow*). There is normal bilateral enhancement of the tympanic segment of the facial nerve.

VIEW IMAGE

Viral Labyrinthitis

Viral infection of the labyrinth may be a cause of sudden sensorineural hearing loss (SNHL), and damage to the inner ear involves the organ of Corti and the vestibular labyrinth. There is contrast enhancement on MR images caused by breakdown of the normal blood-endolymph barrier.[130] Viral labyrinthitis may be due to a direct viral insult or may be associated with an immune response to the invading pathogen.[136]

Viral labyrinthitis is the most common cause of delayed hydrops syndrome. Meniere's disease is considered a form of delayed endolymphatic hydrops occurring in a normal ear that perhaps has suffered a prior subclinical viral insult. Vestibular atelectasis and idiopathic sudden deafness may also have a viral etiology.

Perinatal Conditions

Every year, several thousand infants are born with impaired hearing or deafness. At least 18% of these cases are caused by a proven congenital viral infection, and a greater number are suspected of having an infectious etiology.[131] Congenital cytomegalovirus (CMV) and rubella are the most widely recognized prenatal viral infections associated with perinatal complications including hearing loss.

Cytomegalovirus Infection

CMV is the most common congenital infection in the United States, occurring in 1% to 2% of live births. More than 95% of these infections are clinically silent. CMV is also the leading cause of human congenital viral infection and hearing loss, and it causes progressive hearing loss in children and sudden deafness in adults. Between 1% and 5% of infants infected with CMV develop cytomegalic inclusion disease, which damages the liver, spleen, brain, eye, and inner ear.[131]

Rubella

Maternal rubella during the first trimester places the fetus at the greatest risk of hearing loss and congenital infection. Rubella is responsible for multiple congenital malformations, including cardiac anomalies, vision loss, and developmental delay.[131]

Copyright © 2003, Mosby, Inc. All rights reserved.

Mumps

Mumps is caused by a paramyxovirus and is transmitted by saliva via the respiratory tract. Clinical manifestations include parotitis, salivary adenitis, pancreatitis, thyroiditis, polyarthritis, and myocarditis. Complications include epididymoorchitis in postpubertal males, prostatitis, nephritis, and meningoencephalitis. Hearing loss is usually unilateral (80%) and develops toward the end of the parotitis.[131] The hearing loss is usually permanent. Vestibular symptoms also occur and tend to resolve over several weeks.

Varicella Zoster Virus

Varicella zoster is an exclusively human virus of the herpes family that produces chickenpox (varicella). The virus can become latent in cranial nerves and dorsal root ganglia, and reactivates decades later to cause herpes zoster (shingles) and postherpetic neuralgia.[137]

Herpes zoster oticus, or Ramsay-Hunt syndrome, results from reactivation of latent virus within the geniculate ganglion of the facial nerve. The latent virus lingers in dorsal roots and can be reactivated by systemic disease, immunosuppressed states induced by therapy, or aging. The first symptom is burning pain in the ear, followed 1 to 4 days later by vesicular eruption on the auricle and external auditory canal in the area of sensory innervation of the facial nerve. Facial paralysis, hearing loss, and vertigo may occur singly or in combination. About one-half of patients have a persistent deficit with facial motor disturbance, and a few sustain complete paralysis. Vestibular symptoms include mild unsteadiness to severe vertigo with nausea and vomiting. Auditory symptoms consist of tinnitus and SNHL.

Enhancement on imaging of the seventh and eighth cranial nerves, the membranous labyrinth, and the pontine facial nerve nucleus may occur in this condition (Fig. 22-48).[138–141] There can also be slight enlargement of the nerve in the lateral aspect of the internal auditory canal.

Measles

Rubeola is a paramyxovirus that causes the clinical syndrome of measles with rash, conjunctivitis, and buccal mucosal lesions called Koplik spots. SNHL is abrupt in onset, is usually bilateral, and occurs at the same time as the macular skin rash. Hearing loss is permanent, and 70% of affected patients have abnormal vestibular responses. Prior to the introduction of measles vaccine, rubeola accounted for 3% to 10% of acquired deafness in children.[131] Pathologic findings include severe degeneration of the organ of Corti, the spiral ganglia, and the vestibular sense organs.

Measles encephalitis occurs once in every 600 to 1000 cases. Subacute sclerosing panencephalitis is a progressive neurologic disorder that is usually fatal. Typically, onset occurs months to years after an attack of measles.

Otosclerosis is also associated with measles. It has been demonstrated that the lytic phase of otosclerosis (otospongiosis) is related to the host's ongoing immunologic response to measles. Under influences that are not yet well understood (e.g., estrogens), the osteolytic process is arrested and changed to osteoblast activity accompanied by new bone formation. If the process takes place within the area of the oval window, it results in fixation of the stapes and conductive hearing loss. When the otosclerotic process is restricted to the cochlea, clinical signs are not as well defined.[142–146]

Labyrinthitis Ossificans

Labyrinthitis ossificans (sclerosing labyrinthitis) is the pathologic ossification of the bony labyrinth and cochlea that occurs as the final product of the repair process following a destructive or inflammatory insult. The most common cause of labyrinthitis ossificans is suppurative bacterial labyrinthitis.[147, 148] Other causes of labyrinthitis ossificans include viral labyrinthitis, advanced otosclerosis, trauma, autoimmune inner ear disease, occlusion of the labyrinthine artery, leukemia, and tumors of the temporal bone.[149]

The progression of suppurative labyrinthitis to labyrinthitis ossificans is divided into three stages. The acute phase is characterized by purulence and a serofibronous exudate in the perilymphatic spaces. In the second stage, there is fibroblastic proliferation, resulting in fibrosis. The third stage includes osteoid deposition and osteoneogenesis.[147]

The most common location for fibrosis and new bone formation in the cochlea is the basal turn region of the scala tympani near the round window.[149] Ossification generally progresses from the basal turn to the cochlear apical turn[150] (Fig. 22-49).

As the membranous labyrinth is replaced by fibrous tissue, CT findings are minimal and consist of an ill-defined

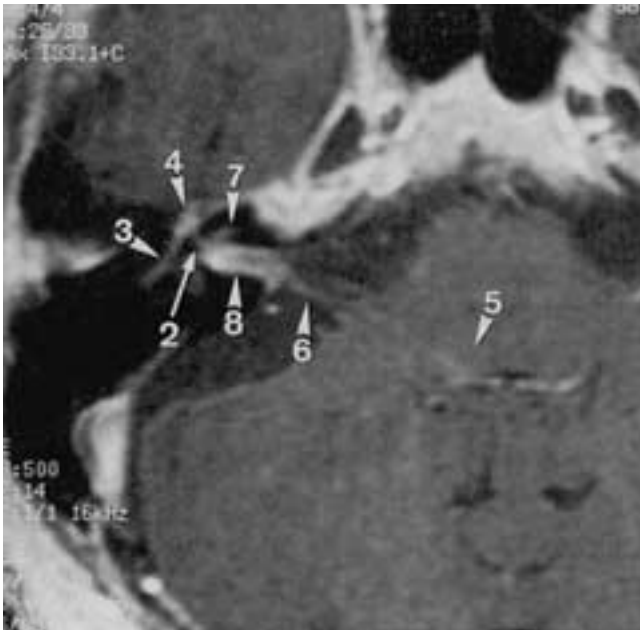

FIGURE 22-48 Ramsay-Hunt syndrome (herpes zoster oticus). A 58-year-old man with acute onset of complete peripheral facial nerve palsy, hearing loss, and vertigo for 28 hours. Postcontrast axial T1-weighted image shows abnormal enhancement of the right facial nerve in the labyrinthine (*2*) segment and normal enhancement of the tympanic (*3*) segment. There is abnormal enhancement of the geniculate ganglion (*4*), the pontine facial colliculus (*5*), the vestibulocochlear nerve (*6*), and the basal turn of the cochlea (*7*). There is also abnormal enhancement of the meninges in the internal auditory canal (*8*). (Reprinted with permission from Sartoretti-Schefer S, Kollias S, Valavanis A. Ramsay-Hunt syndrome associated with brain stem enhancement. AJNR 1999;20(2):278–280.)

VIEW IMAGE

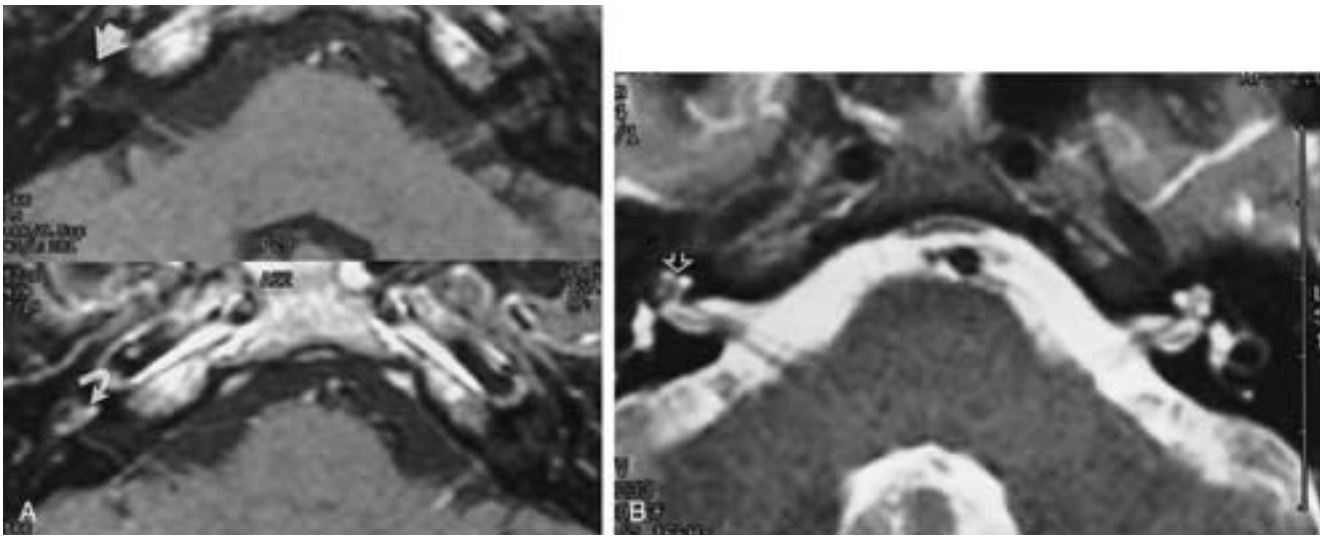
haziness of the membranous labyrinth. However, high-resolution, T2-weighted, fast spin-echo images show loss of normal hyperintensity of the fluid in the membranous labyrinth[151] (Fig. 22-50). The end result is labyrinthine ossification that is easily demonstrated by CT. This process of replacement of fibrous tissue with bone takes place over a period of months to years.[152, 153] Severe labyrinthitis ossificans results in total ''white-out'' of the membranous labyrinth (Fig. 22-51) and the presence of signal void in the labyrinth on T2-weighted images. This appearance may be confused with that of congenital otic dysplasias. The key imaging differential point is the contour of the otic capsule, which is reduced in congenital deformity and maintained in labyrinthitis ossificans[24, 151, 154, 155] (Fig. 22-52). The identification of fibroosseous replacement of the cochlea is of paramount importance when cochlear implantation is contemplated.

Otosyphilis

Syphilis is caused by the spirochete *Treponema pallidum*. Primary acquired syphilis is manifest clinically by a chancre. Secondary acquired syphilis is marked by a cutaneous rash, mucocutaneous lesions, lymphadenopathy, and fever. Tertiary syphilis begins 3 to 10 years after the original infection. Skin, bone, visceral, heart, and central nervous system involvement can occur.

Congenital syphilis, caused by intrauterine infection, is associated with hearing loss in 25% to 38% of patients.



VIEW IMAGE

Clinical manifestations include destructive lesions of the nose (saddle nose), tibial periostitis (saber shins), interstitial keratitis, and dental injury (Hutchinson's teeth). Labyrinthine involvement can occur in congenital syphilis or in the secondary or tertiary stages of acquired infection.

On histopathology, a meningo-neuro-labyrinthitis is found in early infantile congenital syphilis and in the acute meningitides of secondary and tertiary syphilis. Osteitis of the temporal bone with secondary involvement of the membranous labyrinth occurs in late congenital, late latent, secondary, and tertiary acquired syphilis.[131]

Both Meniere's disease and congenital syphilis are known to produce progressive endolymphatic hydrops and have similar clinical expressions. Clinical findings include (1) severe episodic vertigo, (2) fluctuating hearing loss temporally related to vertiginous attacks, (3) low-frequency hearing loss in the initial stages, and (4) flat audiometric patterns in later stages of disease.

The assumption is that these symptoms are the result of overaccumulation of endolymph, with episodic features caused by rupture of the walls of the membranous labyrinth.[10] Vertigo and nystagmus provoked by exposure to high-intensity sound, known as Tullio's phenomenon, can occur in association with congenital syphilis.[10] Tullio's phenomenon may be caused by the development of a third mobile window within the bony labyrinth that permits transmission of vibration to the vestibular apparatus. The first two mobile windows are the oval and round windows. Under normal physiologic conditions, sound pressure is transmitted to the stapes through the oval window and is dissipated at the round window. Dehiscence of bone in the labyrinth creates an alternative path for dissipation of sound through the vestibular apparatus and this allows motion within the perilymph of the semicircular canals, producing the sensation of vertigo.[156]

The osteitis of luetic otosyphilis is characterized by a permeative, or ''moth-eaten,'' demineralization seen on CT (Fig. 22-53). The differential diagnosis of demineralization of the cochlea includes otosyphilis, otosclerosis, Paget's disease, and osteogenesis imperfecta. The bone destruction of Paget's disease is usually diffuse and homogeneous. Bone involvement in otosclerosis and osteogenesis imperfecta is more plaque-like.[23]

Lyme Disease

Lyme disease is caused by the spirochete *Borrelia burgdorferi*, which is transmitted by deer ticks. The initial manifestation is a rash, erythema migrans. Later symptoms include arthritis and myocarditis. Late CNS manifestations

Copyright © 2003, Mosby, Inc. All rights reserved.

consist of multiple neuropathies, including SNHL, and meningitis.[157, 158] Lyme disease is a common cause of facial paralysis, responsible for 50% of cases of acute facial paralysis in children.

Autoimmune Inner Ear Disease

The brain and labyrinth possess blood-brain and blood-labyrinthine barriers that isolate them from most systemic immune responses. Both the brain and the inner ear lack lymphatic drainage.[159, 160] The immuno-isolation of the inner ear can be violated because of the existence of resident lymphocytes around the endolymphatic sac or by entry of circulating leukocytes through the spiral modiolar vein.[159] Autoimmune disease of the ear may be the result of organ-specific disease, or the cochlea may be an innocent bystander of the immune response to other systemic autoimmune diseases, such as systemic lupus erythematosus, polyarteritis nodosa, rheumatoid arthritis, Cogan's syndrome, or polymyositis.[136, 159–161]

The inner ear is more commonly affected in women than in men and, when involved, there is a rapidly progressive SNHL that occurs over a period of several weeks. The hearing loss is usually bilateral (79%).

Autoimmune inner ear disease is characterized by fluctuating, progressive SNHL that responds to immunosuppressive drugs. Antigen-nonspecific screening tests include elevated erythrocyte sedimentation rate, positive autoantibodies (rheumatoid factors, anti-nuclear and anti-thyroglobulin antibodies), circulating immune complexes (IgG, IgM, IgA), and complement levels. Antigen-specific tests include the lymphocyte transformation test and the lymphocyte migration inhibition test. The Western blot analysis for cochlear antigens is also a promising test.[126, 161]

The following pathologic features characterize autoimmune inner ear disease: (1) acute labyrinthitis resulting in atrophy of inner ear tissues, including the sense organs and their supporting structures; (2) endolymphatic hydrops; (3) focal and diffuse proliferation of fibrous tissue and bone in the labyrinth; and (4) retrograde neuronal degeneration of the vestibular and cochlear branches of the eighth nerve.[151, 154, 162, 163]

Polyarteritis Nodosa

Polyarteritis nodosa is a systemic disorder affecting small and medium-sized arteries. The cochlea is rarely affected; SNHL may be the only presenting symptom. Arteritis involving the internal auditory artery, with ischemic changes in the vestibule and cochlea, has been reported, with fibrous tissue and osteoneogenesis in the basilar turns.[159]

Wegener's Granulomatosis

The clinical triad of Wegener's granulomatosis consists of necrotizing granulomas with vasculitis of the upper and lower respiratory tracts, focal necrotizing glomerulonephritis, and systemic vasculitis of the small arteries and veins. The disease is found almost exclusively in Caucasians, with a peak incidence in the fifth and sixth decades.

Wegener's granulomatosis frequently first presents with otologic symptoms that often involve the middle ear and mastoid. Otitis media and conductive hearing loss may result from obstruction of the ET, and SNHL is also common. Histopathologic studies suggest vasculitis involving the cochlear arteries and endolymphatic sac.[159, 161, 164]

Relapsing Polychondritis

Relapsing polychondritis is a disease of unknown etiology characterized by episodic inflammatory necrosis affecting the cartilaginous structures of the ears, nose, upper respiratory tract, and peripheral joints.[159] Airway obstruction may result from loss of cartilaginous support of the trachea. The pinna is red, tender, and edematous, with sparing of the external auditory canal. Vestibuloauditory symptoms point toward an immune-related disease.[161]

Systemic Lupus Erythematosus

Systemic lupus erythematosus has protean manifestations including polyarthralgia, arthritis, pleuritis, pericarditis, pneumonitis, myocarditis, nephritis, cranial nerve palsies, stroke, retinal degeneration caused by vasculitis, and inflammatory bowel disease. The otologic abnormalities include chronic otitis media with necrotizing vasculitis, progressive dysequilibrium, and SNHL.[159, 161]

Rheumatoid Arthritis

In patients with rheumatoid arthritis, both conductive hearing loss and SNHL can occur. The SNHL is probably related to circulating immune complexes.[161] The conductive hearing loss can be explained by middle-ear stiffness secondary to involvement of the synovial joints of the ossicles.

Cogan's Syndrome

Cogan's syndrome is a rare disease of young adults characterized by interstitial keratitis and audiovestibular dysfunction. The median age of onset is 22 years, and there is no gender predilection. Ocular symptoms include photophobia, lacrimation, and eye pain.[160] Vestibuloauditory symptoms are similar to those of Meniere's disease and are progressive.[161] Symptoms include vertigo, ataxia, tinnitus, nausea, vomiting, and hearing loss. Cogan's syndrome may be accompanied by a systemic vasculitis of large and medium-sized vessels, and aortitis usually leads to aortic insufficiency. Involvement of the major vessels arising from the aorta causes stenosis, occlusion, and aneurysm formation. Occlusion of the coronary arteries also can occur.[162]

Immunologic mechanisms play a role in the pathogenesis of this disease, and corticosteroids are the mainstay of therapy.[161] Patients with bilateral deafness may benefit from cochlear implants.

The temporal bone pathology in Cogan's syndrome shows changes that are similar to those observed in other autoimmune disorders (including polyarteritis nodosa, relapsing polychondritis, and autoimmune inner ear disease) associated with audiovestibular dysfunction. Formation of intralabyrinthine fibrous tissue is more frequent and precedes new bone formation. CT scans will detect bony obliteration, but MR will show soft-tissue replacement of the membranous labyrinth. On T2-weighted images, there is loss of the normal high signal intensity of the fluid-filled labyrinth. T1-weighted hyperintensity is attributed to hemorrhage, and contrast enhancement has been reported.[154]

VIEW IMAGE

FIGURE 22-54 Air in the vestibule. Axial image demonstrates a collection of air within the vestibule (*arrow*). This is of profound significance because it indicates a direct communication between the middle and inner ear.

Perilymph Fistula

Perilymph fistula, an abnormal communication between the inner ear and middle ear, can cause vertigo and hearing loss.[165] Though not an infection or inflammation, it is mentioned here because of its relationship to potential movement of infection from the middle ear to the inner ear and potentially to the CSF. The leakage of perilymph should be considered a type of CSF otorrhea and can result in meningitis.[166] Perilymph fistulas may be the result of trauma, surgery, or congenital anomalies. Common sites include the oval and round windows. These fistulas have also been called perilymphatic gushers and oozers, depending on the size of the defect. Patent cochlear aqueducts or small defects in the fundus of the IAC have been implicated as the cause of oozers, a milder welling type of flow. A gusher, a jet-like flow, is probably the result of a larger defect in the fundus of the IAC.[10, 167]

Clinically, a perilymph fistula should be suspected when a patient complains of sudden onset of vertigo after stress, such as barotrauma, head injury, exertion, or air bag trauma. Barotrauma occurring during descent while flying, forced Valsalva maneuver, nose blowing, or suppressed sneezing produces an implosive force on the labyrinthine windows. Lifting, straining, coughing, and sneezing can cause a dramatic increase in CSF pressure that is transmitted via the vestibule to the oval window annulus and the round window membrane. Fracture of the stapes footplate, producing a perilymph fistula, has been reported following suppressed sneezing and childbirth. Also implicated are postoperative complications of stapes surgery for otosclerosis.

There may be a congenital defect in the stapes footplate that occurs alone or in association with other anomalies such as Mondini's dysplasia. The perilymph fistula in Mondini's dysplasia is caused by congenital defects in the modiolus and oval window. The diagnosis of postoperative perilymph fistula is crucial to the surgeon, because repair must be planned to prevent labyrinthitis and possible meningitis. The CT diagnosis is difficult and depends on fluid dynamics within the vestibule. Unexplained dependent middle ear or mastoid fluid collections emanating from the oval window should be viewed with suspicion, and a pneumolabyrinth is obviously highly suggestive in this context (Figs. 22-54 and 22-55). Unfortunately, there may be no CT findings in these cases. Enhanced T1-weighted MR images may demonstrate diffuse enhancement of the membranous labyrinth, suggesting labyrinthitis. Segmental enhancement has also been identified at the site of the perilymph fistula, presumably within granulation tissue.[125, 129, 132]

Intralabyrinthine enhancement also may be secondary to a schwannoma.[168, 169] A schwannoma occurs most commonly in the vestibule and such enhancement is ordinarily quite intense, in contrast to the relatively faint contrast enhancement noted in patients with labyrinthitis. Neoplastic

enhancement persists, and the symptoms are typically nonremitting.[126]

EXTERNAL EAR

External Otitis

External otitis is a common condition also known as swimmer's ear. The condition is caused by many pathogens, and when associated with fungal growth, the condition is called otomycosis. Rarely, first branchial cleft anomalies are the cause of chronic external otitis. First branchial cleft anomalies may appear as a parotid cyst or sinus tract that drains into the external auditory canal.[23, 170] Branchial cleft cysts are discussed further in Chapter 35.

The CT identification of abnormal soft-tissue debris in the external auditory canal (EAC) is not uncommon, is of variable clinical significance, and in most cases is histologically nonspecific. On CT, cerumen is often seen within the EAC as isolated areas of soft-tissue-density material. Simple otoscopic manipulation can cause transient mucosal thickening within the canal, which may cause imaging confusion unless such a history is available. Although the clinician can visualize granulation tissue or fibrous tissue, the medial extent of such debris is usually not apparent otoscopically. In these cases, CT may demonstrate continuity of the EAC disease with the middle ear.

Necrotizing External Otitis

Necrotizing external otitis (malignant external otitis) is an aggressive, resorptive osteomyelitis of the temporal bone (Fig. 22-56).[171–175] This is a disease of elderly diabetics with poor control of diabetes. Culture classically reveals *Pseudomonas aeruginosa*, although *Staphylococcus epidermidis* has also been implicated.[176] Necrotizing external otitis in patients with AIDS occurs in a significantly younger and nondiabetic population. *P. aeruginosa* is not the predominant pathologic organism. Other pathogens, such as *Aspergillus*, are found, and the outcome in AIDS patients is significantly worse than in immunocompetent patients.[177–179]

The term *malignant external otitis* was first coined by Chandler in 1968.[180] The word malignant was chosen to describe the high mortality associated with this disease prior to the availability of effective antibiotic therapy. Because this is an infection and not a malignant process, more appropriate pathophysiologic terms include *necrotizing external otitis* or the more inclusive description *skull base osteomyelitis*.[181] Patients often experience exquisite otalgia or deep pain, and symptoms may begin after irrigation of the external canal with tap water for impacted cerumen.[182]

P. aeruginosa is a gram-negative, motile aerobic rod that tends to proliferate in moist, devitalized tissue, particularly when host defenses are impaired.[183] The exact cause is obscure, although excessive moisture, hyperglycemia, and ischemic perichondritis all have been postulated. This organism produces a variety of endotoxins, exotoxins, neurotoxins, and destructive enzymes. Among the last, elastase and collagenase are the most significant because they allow invasion across fascial planes. The increased severity of this process in diabetic patients is presumably related to poor tissue microcirculation and defective chemotaxis of leukocytes.[182]

Necrotizing external otitis often begins in an insidious fashion at the osseous-cartilaginous junction as a focal area of ulceration and osteitis of the EAC. The TM is resistant to the infectious process, but the disease extends inferiorly via tiny clefts in the cartilaginous portion of the EAC, the fissures of Santorini, allowing access to the soft tissues beneath the temporal bone around the stylomastoid foramen and the infratemporal fossa. The infection may extend into the parotid gland, TMJ, soft tissues of the neck, and skull base.[181, 182] Involvement of the mastoid, middle ear, and petrous apex may also occur.

Facial palsy is a grave prognostic sign and may occur as a

result of mastoid destruction or, more commonly, as a result of subtemporal spread of infection to the stylomastoid foramen. Further medial extension can involve the nerves exiting the jugular foramen as well as the hypoglossal nerve. Intracranial involvement can result from extension through the petrooccipital (petroclival) synchondrosis and may be a preterminal event leading to the development of meningitis, abscess formation, infarcts, or sinus thrombosis.

Both CT and MR imaging provide excellent delineation of soft-tissue invasion in the subtemporal region and give accurate information about the status of the stylomastoid foramen. CT is needed for the evaluation of cortical bone and details regarding involvement of the middle ear, mastoid, and intratemporal bony facial nerve canal.[184–186] Because the soft tissues inferior to the external auditory canal are most often involved, CT or MR imaging in the coronal plane is advantageous to show alteration of the normal fat surrounding the canal as well as the fat planes beneath the more medial skull base. When intracranial pathology is suspected, MR imaging is superior to CT, and dural enhancement and abnormalities of the skull base medullary bone are best appreciated on MR images.[182] Because of its high sensitivity, radionuclide evaluation has a role in the initial diagnosis of this disease.[171]

Pathologically, there is a combination of osteoclastic bone resorption, active new bone formation, and bone necrosis. The differential diagnosis includes malignancy and osteoradionecrosis.

Osteomyelitis of the skull base is usually secondary to inadequately treated necrotizing otitis externa in diabetic or immunocompromised patients. Skull base osteomyelitis may also occur after surgical drainage of a mastoid infection, and rarely as a complication of a sinonasal infection, and there is an increased incidence associated with AIDS.[181, 187–191] Infection extending to the skull base foramina results in cranial nerve palsies, and these patients usually present with unremitting headache in the temporal region. A conductive hearing loss is another common symptom due to middle ear fluid secondary to ET dysfunction. A change in voice quality and dysphagia are usually the initial symptoms of vagal nerve involvement. In descending order of occurrence, abnormalities of cranial nerves 12, 11, and 9 follow, with associated difficulty with speech and swallowing and weakness of the shoulder.[189] Intense inflammation around the jugular fossa may also produce jugular vein and sigmoid sinus thrombosis.[190]

Although *Pseudomonas* is the usual pathogen in skull base osteomyelitis, *Aspergillus*, *Staphylococcus aureus*, *S. epidermidis*, *Proteus*, and *Salmonella* have also been implicated.

A technetium bone scan can identify osteomyelitis before bone destruction is identified on CT scans. Because bone repair may continue long after the infection has resolved, the technetium bone scan has limitations for therapeutic monitoring, as it will remain positive long after the osteomyelitis has cleared.[181]

More advanced cases demonstrate bone destruction and bone sequestration on CT (Fig. 22-57). Soft-tissue edema and abscess formation in the parapharyngeal space and nasopharynx can also occur. CT is of little use in determining resolution of the bone infection, as remineralization is a slow process and the destroyed bone may never return to a normal appearance.[181]

Although MR is superior to CT in the detection of marrow abnormalities and soft-tissue changes, MR is not useful in evaluating the response to therapy, as the marrow changes caused by inflammation may take up to 6 months to return to normal. Similarly, gallium-67 studies may also take up to 6 months to return to normal after successful therapy. Currently, CT and bone SPECT scintigraphy are the best methods for detecting osteomyelitis in areas of the skull that have little or no bone marrow. Indium (In-111) 111 WBC and Tc-99m MDP bone SPECT are best for detecting osteomyelitis in patients with cranial base alterations resulting from changes such as surgery.[187, 188] A combination of In-111 WBC and Tc-99m SPECT may be the best imaging approach to assess the posttherapeutic response, as abnormal findings revert to normal sooner with In-111 WBC

FIGURE 22-58 Osteoradionecrosis. There is destruction of bone in the EAC with a sequestrum (*arrow*).

scanning than they do with gallium, MR, or CT in successfully treated patients.[187] In-111 WBC scintigraphy may become normal while the patient is being treated with antibiotics, and a follow-up scan 4 weeks after completion of therapy may provide the most reliable assessment of the therapeutic outcome.[23]

Differential Diagnosis and Other Lesions

Osteoradionecrosis

SNHL and osteoradionecrosis are late sequelae of irradiation of the temporal bone. SNHL is due to atrophy of the membranous labyrinth and spiral ligament, with degeneration of the organ of Corti. Osteoradionecrosis is a slowly destructive process that may be confused with malignancy, osteomyelitis, or necrotizing external otitis. There is destruction of bone with sequestration[192] (Fig. 22-58). Symptoms of otalgia and persistent otorrhea begin as early as several months to as late as many years after radiation therapy.[193–196]

Malignancy

The pathology most commonly confused with necrotizing external otitis is malignancy. The malignancies involving the EAC may arise within the canal or extend to it from surrounding structures. The most common histologies are squamous cell and basal cell carcinomas and minor salivary gland carcinomas.[100, 197, 198] Melanomas, metastases, and gliomas are rare.

Squamous cell carcinoma, a disease primarily of the elderly, may originate in the canal or extend to it from the middle ear. In the latter circumstance, there usually is a long-standing history of chronic otitis media. Squamous cell carcinoma may simulate necrotizing external otitis with regard to symptoms of pain and ear drainage, otoscopic findings, and bone destruction on CT. Histologic examination is therefore mandatory in all patients with suspected malignant external otitis.[199]

Basal cell carcinoma invading the external auditory canal often originates in the postauricular sulcus. Neoplasms of salivary origin (i.e., mucoepidermoid carcinoma, adenoid cystic carcinoma) may originate in the parotid gland or may arise from minor salivary gland rests within the external canal or middle ear.

Tumors of Ceruminous Gland Origin

There are two types of sweat glands in the body: eccrine (which have a generalized distribution) and apocrine (which have a limited distribution). The apocrine glands located within the EAC are referred to as ceruminous glands. The normal cerumen produced in the EAC is a mixture of secretions from both ceruminous and sebaceous glands, and

its acidic and chemical composition is thought to aid in avoiding infections.

The tumors of ceruminous gland origin include ceruminous adenoma, pleomorphic adenoma, adenoid cystic carcinoma, mucoepidermoid carcinoma, and ceruminous adenocarcinoma. Adenomas and pleomorphic adenomas are rare tumors of the EAC, with adenoma being more common. Both tumors occur in the fourth to sixth decades of life and can develop anywhere in the EAC. The CT findings of a soft-tissue mass in the EAC without bone destruction are nonspecific. Adenoid cystic carcinoma and adenocarcinoma are much more aggressive lesions.[23]

Exostosis and Osteoma

The most common benign ''neoplasm'' of the external canal is the exostosis.[200, 201] (Fig. 22-59). This lesion arises in the medial aspect of the osseous portion of the EAC, near the tympanic annulus, usually in patients with prolonged exposure to cold sea water or swimming pool water. As such, vasodilation is believed to play a causative role. Bilateral exostoses are common, the lesions are often broad based, and they usually arise along the tympanomastoid or tympanosquamous suture lines. Interestingly, they do not occur in African Americans.

Although clinically similar, the exostosis is distinct from an osteoma, which is much less common and usually unilateral. Osteomas are pedunculated bony growths, usually found lateral to the isthmus of the IAC (Fig. 22-60). Other temporal bone sites occur, in particular the mastoid.[23, 202] Although the mass is readily apparent on otoscopic examination, CT can define the entire extent of the lesion and evaluate middle ear disease.

Cholesteatoma and Keratosis Obturans

Keratosis obturans (KO) and external auditory canal cholesteatoma (EACC) both represent accumulations of exfoliated keratin within the EAC. Although there is controversy about the exact definitions, many believe that they are entirely different clinical and pathologic processes.[174, 175, 203]

FIGURE 22-60 Otoscopy. Osteoma is a pedunculated mass in the EAC.

VIEW IMAGE

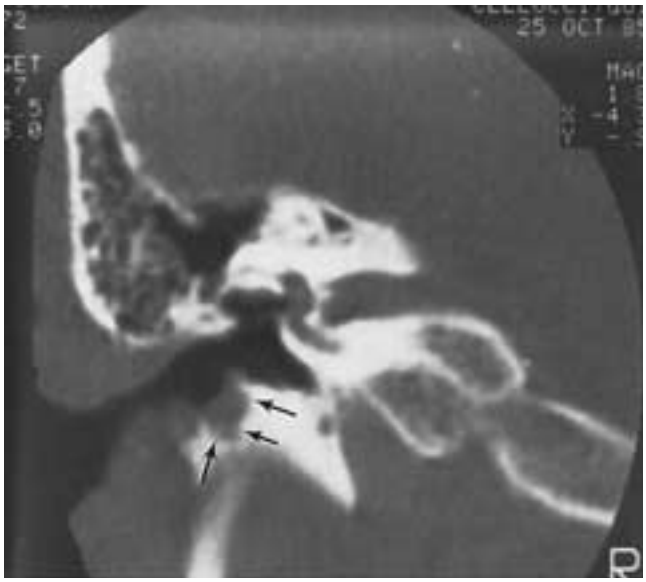

FIGURE 22-61 EAC cholesteatoma. There is a soft-tissue mass in the EAC. ''Punched-out'' erosions in the floor of the EAC are demonstrated on this coronal image (*arrows*).

VIEW IMAGE

Cholesteatomas occur almost exclusively in the middle ear and mastoid. However, cholesteatomas occasionally arise in the EAC in 0.1% to 0.5% of otologic patients.[204] Patients typically present between the ages of 40 and 75 with a history of persistent otorrhea and chronic dull otalgia. Otoscopic findings show erosion of the osseous EAC with squamous debris, granulation tissue associated with periostitis, and necrotic bone (Fig. 22-61). Sequestra may occur. The process is usually unilateral. Although the cause of cholesteatoma of the EAC is unknown, a periostitis of the bone of the canal is frequently implicated as the initial abnormality. Invasion of the squamous epithelium follows, and the cholesteatoma is formed. The location is typically along the posterior inferior wall of the canal just lateral to the TM. There may be an accumulation of keratin, giving a mass appearance with erosion of the canal wall, or the lesion may have the appearance of an ulcerated cavity lined by squamous epithelium. The cholesteatoma is considered to be a more localized lesion than the KO, which fills the entire canal with debris.

KO usually is diagnosed in patients under the age of 40 years who have a history of sinusitis or bronchiectasis. There often is severe pain and conductive deficit, but otorrhea rarely occurs. KO is often bilateral, associated with an abnormal TM, and heralded by a keratin plug and smooth widening of the canal on otoscopic inspection (Fig. 22-62). By comparison to the cholesteatoma, the keratin plug of KO fills the canal rather than extending into the wall of the canal, and the bony wall is expanded outward rather than destroyed. The pathogenesis of KO is unknown. One theory proposes that bronchiectasis may produce sympathetic reflex stimulation of ceruminous glands in the EAC, leading to hyperemia and the formation of the epidermal plug. Another theory suggests that abnormal pathways of epithelial migration are responsible.[205]

VIEW IMAGE

FIGURE 22-62 KO. Coronal (**A**) and axial (**B**) scans reveal smooth expansion and erosion of the canal wall (*arrows*).

CT is of value for determining the extent of disease and for aiding in the differentiation of these entities, as patients with KO may show gradual widening of the EAC with an intact smooth cortex, while patients with cholesteatoma tend to have an irregular invasion of bone. Because the mastoid segment of the facial nerve canal is located immediately adjacent to the posterior tympanic annulus, axial CT is well suited for determining the proximity of disease to this crucial structure.

POSTOPERATIVE TEMPORAL BONE

CT has become an indispensable tool for evaluating the postoperative middle ear and mastoid.[52, 53, 206, 207] This examination is especially helpful when the surgery was performed many years ago or by a surgeon other than the one referring the study. CT should be routinely recommended in the evaluation of the symptomatic postmastoidectomy patient. It is also wise to recommend that a baseline CT scan be obtained (with which future studies can be compared) in the recently operated asymptomatic patient. CT is also informative for evaluating the prosthetic stapedectomy and other forms of ossiculoplasty.[53, 103, 208]

Mastoidectomy

Regardless of the exact surgical approach (postauricular, endaural, transcanal), the object of surgery for chronic otitis media and cholesteatoma is to remove all diseased tissue while sparing as many normal structures as possible.[209]

A structured CT evaluation of the postmastoidectomy patient should include (1) categorization of the surgical defect (Table 22-6), (2) evaluation of the cavity for residual debris, (3) careful study of the margins of the cavity for bony defects, (4) observation of the status of the ossicular chain, (5) evaluation of the inner ear structures to exclude fistula formation, and (6) careful study of the margins of the facial nerve canal. Removal of air cells with maintenance of the EAC wall and ossicular chain (OC) constitutes a simple (cortical) mastoidectomy (Fig. 22-63A). The simple (cortical) mastoidectomy has fallen into disrepute.

Removal of all mastoid air cells with sparing of the EAC wall and OC is termed an intact canal wall mastoidectomy (ICWM) or canal wall up mastoidectomy (Fig. 22-63B).[210, 211] In this procedure Koerner's septum is removed, providing access to the attic and antrum. This procedure is used for cholesteatoma in children with well-pneumatized mastoids.[24] It avoids the tympanomastoid cavity; however, published recurrence rates are unacceptably high. These procedures are categorized as closed-cavity mastoidectomies.

The open-cavity procedures (radical mastoidectomy, modified radical mastoidectomy) are encountered much more commonly.[210, 212, 213] The EAC wall is removed with a canal wall down (open cavity) mastoidectomy. Resection of the scutum allows access to the attic. Thus, there is

Table 22-6
MASTOIDECTOMY CLASSIFICATION

Closed cavity (canal wall up) EAC intact
Simple (cortical) mastoidectomy (limited removal of mastoid air cells)
Intact canal wall mastoidectomy (removal of all mastoid air cells)
Open cavity (canal wall down): resection EAC
Modified radical mastoidectomy (ossicular chain preserved)
Radical mastoidectomy (ossicles removed but stapes preserved)
To access IAC
Translabyrinthine approach (canal wall up mastoidectomy, removal of semicircular canals and of bone over sigmoid sinus)
Retrosigmoid approach (subocciptial craniotomy, removal of posterior wall IAC)

communication between the mastoid cavity and the EAC. In the modified radical mastoidectomy (Bondy procedure), which is performed primarily for atticoantral cholesteatoma, the OC is meticulously preserved and reconstructed (Fig. 22-63C). For this reason, both preoperative and postoperative CT evaluation should include an investigation of the status of the stapes superstructure.

A radical mastoidectomy is necessary for more extensive disease. It includes removal of most of the OC, with preservation of the stapes (Fig. 22-63D).

Access to the IAC also can be via a mastoidectomy. In the translabyrinthine approach, a canal wall up mastoidectomy is performed, and the facial nerve is skeletonized and preserved. The semicircular canals are resected, along with the bone covering the sigmoid sinus and adjacent dura of the middle and posterior cranial fossa. This approach allows access to the posterior aspect of the IAC and is used to remove acoustic schwannomas in patients with irreversible hearing loss (Fig. 22-64).[214]

In the retrosigmoid approach, a suboccipital craniotomy is performed and the posterior wall of the IAC is removed, allowing access to the intracanalicular seventh and eighth nerves and the cerebellopontine angle. Hearing may be preserved with this approach, as the middle and inner ear structures are not involved in the procedure.[214]

It is virtually impossible to make a histologic diagnosis of debris in a tympanomastoid cavity based on the CT appearance (Fig. 22-65). On CT, recurrent cholesteatoma, granulation tissue, and even simple redundant mucosa or surgical packing may appear identical. However, granulation tissue will enhance intensely on contrast-enhanced MR imaging. As mentioned, a cholesteatoma does not enhance. Fortunately, such a specific diagnosis is not important and the surgeon is much more concerned about associated clinical and imaging findings. Regardless of the histopathology, most debris is identified in the posterosuperior aspect of the cavity, and an attempt should be made to distinguish debris in the mastoid bowl from that in the middle ear or attic proper (deep to or superficial to a tympanoplasty, if present).

Before reoperation, the surgeon will want to ensure that the margins of the cavity are intact. In this regard, focal bony

defects, especially in the region of the tegmen or sigmoid sinus plate, can be especially significant (Fig. 22-65B). Individuals with defects adjacent to the sigmoid sinus plate are at risk for the development of sigmoid sinus thrombosis should complications arise. A mass protruding downward through a defect in the tegmen may represent a cephalocele, and the presence or absence of brain within the mass is easily identified with MR imaging.[24] In the presence of bony defects, MR imaging is strongly recommended to evaluate the adjacent cerebellum and sigmoid sinus.[215]

The margins of the OC must be carefully studied, particularly if the surgeon plans a definitive procedure that may include tympanoplasty and ossiculoplasty. In this regard, the distal incus is especially vulnerable in the preoperative patient with a long history of chronic otitis media. The otic capsule, particularly over the lateral semicircular canal, should be carefully evaluated for thinning that suggests fistula formation. The facial nerve canal, particularly in the mastoid segment, may be dangerously close to the surgical defect, and the referring physician should be cautioned. Occasionally, a defect in the canal may be seen along the lateral aspect.

Under unusual circumstances, the contents of a nonoperated acquired cholesteatoma may drain externally, leaving only the aggressive peripheral microscopic membrane, which consists of keratinizing stratified squamous epithelium. The CT appearance in these patients simulates a mastoidectomy because no soft-tissue mass is seen. As previously mentioned, this is variously referred to as automastoidectomy, mural cholesteatoma, and cholesteatoma ''shell'' (Fig. 22-32A,B).[216] The smooth outline of the defect follows the original wall of the cholesteatoma. There is a continuity of the cavity with the EAC. The term autoatticotomy has been used to describe smaller defects where only the scutum and lower lateral attic wall are absent.

Ossiculoplasty and Ossicular Reconstruction

The purpose of ossiculoplasty is to rebuild the sound-conducting mechanism of the middle ear. Damage to this mechanism most likely is caused by chronic otitis media, cholesteatoma, trauma, or congenital ossicular malformation.[217–219] This reconstruction consists of medialization of the TM or creation of a prosthesis to reestablish continuity between the TM and the remaining OC or oval window. Autograft prostheses are tissues harvested from the patient and include rib cartilage, tragal cartilage, and incus. Homograft prostheses are obtained from human donor tissue. Examples include TM, ossicles, and total or partial cartilaginous ossicular reconstruction prostheses. Allograft protheses are biocompatible synthetic materials. A number

of materials are used, including high-density polyethylene sponge (Plastipore), aluminum oxide ceramic, and hydroxyapatite, as well as various other products.[220–222] Most of these devices are nonferromagnetic and are not a contraindication to MR imaging.[223]

The most common sites of ossicular discontinuity are the incudostapedial joint and the lenticular process of the incus. If the incus is missing or unsalvageable, ossicular reconstruction prostheses (ORP) may be employed. If the stapes is intact, with a mobile footplate, a partial ossicular reconstruction prostheses (PORP) (Fig. 22-66) is used. Incus interposition involves removal of the incus (or its remnants), then sculpting and drilling it so that the redesigned incus can be interposed between the TM and the intact stapes superstructure (Fig. 22-67). The absence of both incus and stapes requires a total ossicular replacement prosthesis (TORP). The TORP is interposed between the TM and the oval window (Fig. 22-68).

A stapes prosthesis is the most common ossicular reconstruction and is performed to restore conductive hearing loss in individuals with fenestral otosclerosis or congenital abnormalities.[219, 224] Many different types are in use, including Teflon, wire, Silastic (silicone), and stainless steel piston devices.[23]

Protheses made of 35-gauge wire are especially difficult to see on CT, although usually the tip of the wire can be

identified with overlapping, thin axial scans (Fig. 22-69).[103] The metallic piston prosthesis is easily seen in all projections (Figs. 22-70 to 22-72). Identification of the Teflon and Silastic devices is intermediate in difficulty (Fig. 22-73).

Causes of postoperative hearing loss include prosthesis subluxation, incus necrosis, granuloma or fibrous tissue formation, or recurrent growth of otosclerosis and incus dislocation. The prosthesis need not be located centrally in the oval window to be effective. The normally functioning prosthesis may be located in the anterior, central, or posterior portion of the oval window (Fig. 22-70). By comparison, displacement of the prosthesis superficial to the oval window or into the vestibule implies malposition (Fig. 22-71). Audiometric evaluation is much more sensitive in this regard.[24]

The most common cause of correctable prosthetic failure is subluxation or dislocation, which is seen in 50% to 60% of patients with postoperative hearing loss.[219] The CT finding in cases of prosthesis subluxation is a ''vacant'' oval window. Careful evaluation of the posterior recesses and ridges in the axial projection usually yields evidence of the dislocated prosthesis itself (Figs. 22-74 and 22-75).

Incus necrosis may occur at the attachment of the wire to the long process.[184, 225] The CT diagnosis is difficult and depends on careful evaluation of high-quality overlapping

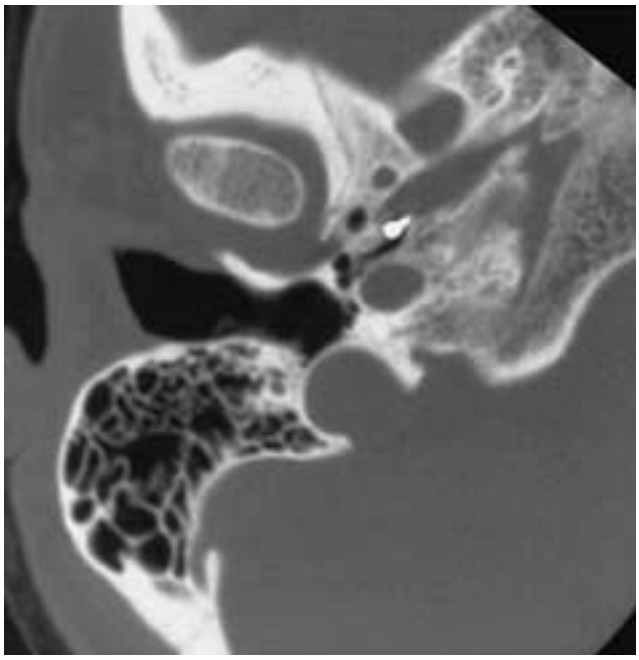
coronal images (Fig. 22-76).[53] Any defects in the long process should be viewed with intense scrutiny.

Possible complications of ossicular reconstruction include dislocation or postinflammatory fixation (or both) by granuloma or fibrous tissue formation. CT is quite valuable in the postoperative evaluation of these patients.[52, 218, 226] Postoperative debris found near the oval window more than 4 to 6 weeks after surgery in the presence of persistent or recurrent conductive hearing loss must be regarded with suspicion for granuloma formation or tympanic fibrosis.[23]



VIEW IMAGE

FIGURE 22-72 Stapes prosthesis. Dislocated metallic piston stapes prosthesis in the ET.

Such tissue may also develop more laterally at the incal attachment and is especially likely to occur in individuals with preexistent chronic otitis (prosthetic stapedectomy in individuals with tympanosclerosis has a much higher incidence of poor surgical results).[53]

Continued growth of otosclerotic plaques can cause further narrowing of the oval window and thus compromise function of the prosthesis. Although a specific diagnosis often can be inferred when this occurs, in the absence of preoperative images it is quite difficult to make a CT diagnosis. CT is often requested for evaluation of recurrent conductive deficit, vertigo, and SNHL in the poststapedectomy patient.[211, 224, 225] Vertigo and SNHL are common in the immediate postoperative period and are usually self-limited. However, persistent or recurrent and fluctuating symptoms of this type may have significant implications, such as the presence of a perilymphatic fistula. Perilymphatic fistula may be difficult to identify on CT but is suspected in the presence of pneumolabyrinth or a new, unexplained middle ear effusion.[219]

SNHL loss or vertigo also may result from abnormal penetration of the prosthesis into the vestibule with compromise of the utriculosaccular organ. The CT diagnosis may be simple, but it depends on the type of prosthesis used.

Acute labyrinthitis, endolymphatic hydrops, and intravestibular fibrous adhesions are additional causes of poststapedectomy dizziness, vertigo, and SNHL.[227] There are no known CT manifestations. Enhancement of the membranous labyrinth in individuals with labyrinthitis may occur in subacute cases on T1-weighted MR images, and enhancement of the endolymphatic sac has been described in individuals with endolymphatic hydrops.[126] Ossification of the membranous labyrinth may develop in long-standing chronic labyrinthitis.[53] In such a circumstance, the CT findings are quite obvious (Fig. 22-51).

Simple tympanoplasty is performed in individuals with an unhealed perforation of the TM, and CT usually plays no

role in the evaluation of this procedure. Both the homograft and synthetic replacements referred to in the previous paragraphs require tympanoplasty.

Cochlear Implantation

For individuals with severe to profound sensorineural deafness, cochlear implantation has become increasingly available and both single-channel and multichannel devices are in clinical use.[228–230] The electrodes are introduced by making an opening in the basal turn of the cochlea anterior to the round window. The electrodes are usually inserted into the scala tympani for a variable distance to stimulate the cochlear nerve.

Temporal bone imaging has been used for both preoperative and postoperative evaluation. In the postoperative patient in whom placement was technically difficult, CT can be helpful in identifying the site of the electrode tip. However, preoperative evaluation is generally more critical, particularly for the multichannel device, which must be inserted 22 to 26 mm into the middle cochlear turn (Fig. 22-77). Obstruction of the labyrinth by ectopic bone or fibrous tissue is a common consequence of meningitis or labyrinthitis. Absolute contraindications to implantation include bilateral acoustic neuromas, severe fractures, obliterative labyrinthine (cochlear) ossification, and, of course, congenital absence of the cochlear nerve. Relative contraindications include diffuse otosclerosis, obliterative labyrinthitis, hypoplasia of the IAC, congenital cochlear malformations, and uncontrolled otitis media or mastoiditis.[214, 231] Fibrous changes within the membranous labyrinth, which are also a source of surgical difficulty, are not demonstrable by CT. However, thin section MR imaging, utilizing

thin sections and T2-weighting, may be quite informative.[151, 154, 155, 229, 231–233]

IDIOPATHIC FACIAL PARALYSIS (BELL'S PALSY)

The term *Bell's Palsy* refers to a facial paralysis or paresis that has no identifiable cause and therefore is considered to be idiopathic. As inflammation related to a viral infection is the most likely mechanism for the palsy, idiopathic facial paralysis is included in this chapter.

Bell's or idiopathic facial paralysis has a very typical presentation. The weakness is of very rapid onset. Frequently, the patient will wake up with the paralysis, which may progress for several hours or, rarely, up to three weeks. Continued progression beyond that time, however, is distinctly unusual and should suggest another cause of the problem. The paralysis is peripheral and all branches are involved. Almost all patients show some recovery. The Bell's palsy will almost always begin to improve and more than 80% of patients have improvement to a satisfactory level within six months.[234] There are various electrophysiological tests used to follow the progression and look for early or disordered recovery, allowing for a more accurate documentation of the course than does simple physical examination.[234, 235]

Most investigation suggests a viral or viral inflammatory immune mechanism. Many studies point toward the herpes simplex virus but findings are not definitive. A virus may cause swelling of the nerve as the initial insult. The swelling causes compression of the blood supply within the very narrow confines of the bony facial nerve canal. This vascular compromise gives further injury to the nerve and paralysis results.

The narrowest point in the canal is the labyrinthine segment. Thus, insult to the nerve in this region has been suggested as the most likely cause of paralysis.[236] Swelling in the labyrinthine segment extending into the internal auditory canal has been documented during surgical decompression.[236]

Bell's is a diagnosis of exclusion. If a specific cause is determined then the term *Bell's* or *idiopathic* should not be used. Trauma (including birth trauma), various neurologic diseases, specific infections, metabolic diseases, toxins, and tumors can all cause facial paralysis.[235] Tumor is the most important etiology to be excluded. A tumor can occur anywhere along the course of the facial nerve from the brainstem to the peripheral face. The most common locations of tumors presenting as facial paralysis are in the temporal bone and in the parotid gland region, and these are the areas usually examined by imaging in ambiguous cases. Specific viral agents have been identified as causing facial paralysis. For instance, Herpes oticus (Ramsey Hunt syndrome) is caused by herpes varicella zoster virus. This virus produces a very specific presentation (discussed earlier in this chapter) and is not included as a Bell's palsy. If further investigation determines that a specific virus is the responsible etiologic agent for some group of patients carrying the Bell's designation then this group of patients would presumably be taken out of the Bell's category.

Imaging

Many clinicians consider imaging unnecessary in a patient with the typical presentation of Bell's palsy. If the patient has a rapid onset of paralysis and has the typical clinical course, no imaging may be done. It should be remembered, however, that tumors can mimic Bell's palsy so that the classic Bell's presentation does not exclude tumor or other central pathologies. Factors that more strongly suggest tumor include slow onset of weakness and progression beyond a short interval. Failure to have significant improvement by six months or recurrence of an improved paralysis should suggest tumor. Bilateral paralysis should also be considered suggestive of a more central pathology.

MR imaging with gadolinium is the usual choice for evaluation of suspicious cases. High-resolution imaging should focus on the temporal bone but should be continued through the parotid gland. Imaging includes the brain—particularly the brainstem.

The findings in Bell's, or idiopathic facial paralysis, are typical.[234, 237–242] With gadolinium, there is increased enhancement of the facial nerve (Fig. 22-78). Any segment can be involved, but typically there is pronounced enhancement in the region of the geniculate ganglion and in the labyrinthine and anterior tympanic segments of the nerve. There is usually some enhancement in this region normally, but with Bell's the enhancement is increased. The nerve should not be enlarged within the facial nerve canal itself. Enlargement of the segments within the temporal bone suggests tumor. The enhancement continues into the most lateral part of the internal auditory canal. Here the nerve just proximal (medial) to the entrance into the facial canal from the IAC will actually swell and enhance (see Fig. 22-78). This focal enlargement and enhancement can be appreciated on MR imaging and should not be mistaken for tumor. However, in questionable cases a follow-up study is done to ensure that the finding reverts to normal. Recently, high-resolution T2-weighted imaging has also visualized the slight enlargement of the facial nerve in the lateral part of the IAC.[243]

Most specialists consider MR imaging to be the study of choice in facial paralysis. Resolutioin of modern machines allows documentation of the normal size of the nerve. MR imaging is more sensitive than CT in detecting more central pathologies and therefore can more reliably exclude them. The parotid gland is easily evaluated. CT gives high-resolution imaging of the bony canal within the temporal bone. Documentation of a normal canal without expansion and with no eroding lesion is strong evidence that there is no tumor. Small lesions within the IAC can be missed and central pathology is not well evaluated. If CT is done the study should be carried down through the parotid gland to exclude a tumor. CT is also used to clarify an ambiguous finding on MR imaging. Definition of the fine bony detail of the facial nerve canal and surrounding temporal bone may help exclude a tumor if the enhancement seems atypical on MR imaging.

Attempts have been made to use the degree of enhancement as an indicator of prognosis but so far studies have been inconclusive.[239, 241]

Temporal Bone: Trauma

Joel D. Swartz and Hugh D. Curtin

INTRODUCTION
FRACTURES AND PSEUDOFRACTURES
- Longitudinal Fractures
- Transverse Fractures
- Pseudofractures

OSSICULAR DISLOCATION AND FRACTURE
COMPLICATIONS OF TEMPORAL BONE TRAUMA
- Fistulous Communications
- Hearing Loss
- Facial Nerve Dysfunction

INTRODUCTION

Temporal bone trauma usually results from blunt head injury.[1, 2] The discussion in this chapter will be subdivided into the topics of fractures and pseudofractures, ossicular dislocations, and complications of temporal bone trauma. This chapter will also emphasize that in the imaging evaluation of the posttraumatic patient with a possible temporal bone fracture, CT and MR imaging are complementary studies.

FRACTURES AND PSEUDOFRACTURES

Temporal bone fractures follow the paths of least resistance, usually connecting natural fissures and foramina. These fractures are classified by their orientation relative to the long axis of the petrous bone.[2–6] Overall, these fractures are best imaged, especially in the critically injured patient, in the axial CT study.[7] Up until recently, the axial examination was the only plane available for imaging the severely injured patient. However, recent advances such as multidetector spiral CT have made possible multiplanar reformatting from axial image data. These reformatted images approach the resolution of the original image acquisition and allow assessment in various planes without repositioning an unstable patient (Fig. 23-1).

Most observers continue to believe that longitudinal fractures are by far the most common type of temporal bone fracture, followed by transverse, oblique, and mixed-type fractures. There is, however, some dispute on this subject, as some recent investigators have concluded that most of these fractures are actually oblique in alignment.[8] Nonetheless, for the purposes of this discussion, the well-accepted concept that the longitudinal variety is indeed the most common fracture will be used. More severe fractures frequently have components extending both along and perpendicular to the axis of the temporal bone. Fractures associated with gunshot wounds are typically quite complex, and the quality of evaluation may be limited by metallic artifact. Chin-dashboard trauma is associated with less common injuries including tympanic ring fracture and TMJ injury. Styloid process fractures are rare and difficult to diagnose. They often have nonspecific clinical manifestations including headache and upper neck pain.[9]

Longitudinal Fractures

Longitudinal fractures of the petrous temporal bone are parallel to the long axis of the petrous pyramid and are typically associated with a blunt temporoparietal blow[10, 11] (Figs. 23-2 to 23-5). Approximately 10% are associated with a visible ecchymosis over the mastoid process (‘‘Battle’s sign’’). These fractures cross the middle ear and are very frequently associated with ossicular dislocation (see below). As longitudinal fractures follow the paths of least resistance, they are usually extralabyrinthine, most commonly deflecting anteriorly toward the eustachian tube and middle cranial fossa.[2, 12–14] Less commonly, the fracture can deflect posteriorly relative to the labyrinth, exiting the temporal bone through the jugular foramen and extending into the posterior fossa.

Involvement of the external auditory canal (EAC), tegmen tympani, and squamous temporal bone is common, and occlusion of the EAC by bony fracture fragments or soft-tissue debris may preclude otoscopic inspection. Sensorineural hearing loss is unusual unless there is a so-called cochlear concussion or perilymphatic fistula. Perilymphatic

FIGURE 23-1 Longitudinal fracture with multidetector CT and multiplanar reformatting. **A**, Axial plane. The fracture (*arrow*) is oblique to this plane but is seen passing along the roof of the EAC. There is fluid (blood) in the mastoid and middle ear. **B**, Coronal reformat shows the fracture (*arrow*) extending into the middle ear. **C**, Sagittal plane reformat is perpendicular to the fracture line and shows the fracture crossing the tegmen and extending into the external canal (*arrows*). **D**, Sagittal reformat medial to **C** shows fracture *(arrow)* extending into the temporomandibular joint.

fistula may result from implosion or displacement of the stapes footplate or from rupture of the round window membrane. Conductive hearing loss is quite common and is often due to ossicular disruption.

As mentioned, fractures crossing anterior to the labyrinth can pass along the eustachian tube. They can, however, also fracture the thin cortical plate of the carotid canal, be multiple, and continue to extend across the foramen lacerum and reach the sphenoid bone. Rarely, the fracture can cross through the opposite side of the sphenoid, becoming bilateral.[11] Commonly, the sphenoid bone fractures where the carotid artery causes an impression on the lateral sphenoid sinus wall. Thus, the carotid artery is at risk for damage in both the petrous and sphenoid portions of its canal. There is the risk of an arterial tear, a pseudoaneurysm, or a carotid cavernous sinus fistula. Dissection or complete occlusion of the artery can also occur.[12] If CT demonstrates a fracture involving the carotid canal, angiography should be considered. MR angiography and CT angiography are less invasive alternatives to conventional angiography. The artery is placed at significantly increased risk if there is displacement of a bone fragment into the canal or if there is substantial dislocation of the petrous apex.[11]

Longitudinal fractures have been described as having posterior and anterior subtypes, based primarily on the site of origin.[15, 16] The posterior subtype often originates in the mastoid process or posterior aspect of the squamosal portion of the temporal bone and terminates in the foramen lacerum. This fracture usually does not involve the glenoid fossa. The anterior subtype originates in the anterior portion of the squamosal portion of the temporal bone and traverses the tegmen tympani to terminate at the petrous apex or pass again along the eustachian tube to the foramen lacerum. This anterior subtype may result in disruption of the middle meningeal artery with development of an epidural hematoma. The glenoid fossa is typically involved in the anterior subtype.

Both the posterior and anterior subtypes tend to involve the first genu or proximal tympanic segment of the facial nerve, but facial palsy is less common and less severe than palsies associated with transverse fracture (see later in the chapter). Rather than extending across the nerve, the longitudinal fracture may extend along the neural canal itself. Because this fracture does not directly cross the canal, it is unlikely to transect the nerve. Rather, the glancing or shearing effect of the fracture can cause swelling or a

FIGURE 23-2 Drawing of the longitudinal fracture. Note that the fracture line is parallel to the long axis of the petrous bone. (From Swartz JD, Harnsberger HR. Imaging of the Temporal Bone, 3rd ed. New York: Thieme, 1998.)

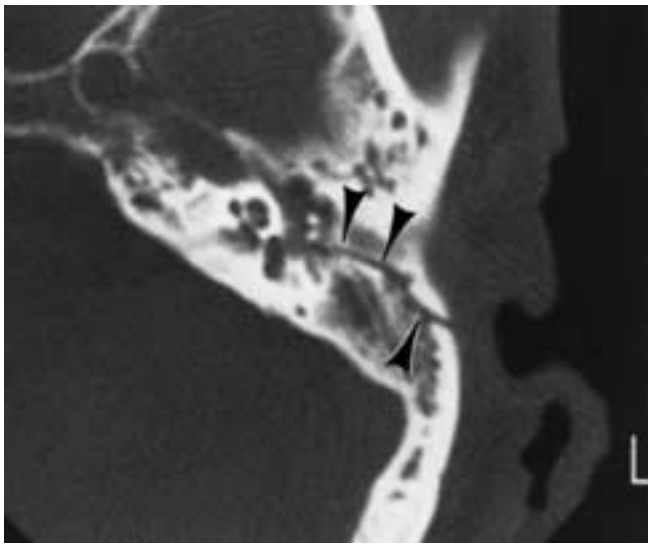

FIGURE 23-4 Longitudinal fracture. Fracture line is demonstrated through the mastoid (*arrowheads*), extending to but not disrupting the ossicular chain. (From Swartz JD, Harnsberger HR. Imaging of the Temporal Bone. New York: Thieme, 1992.)

hematoma in the nerve. Lastly, a fracture fragment may impale the nerve, causing further injury.

In traumatic facial paralysis, the relationship of the time of onset of the paralysis to the trauma is important. A paralysis of immediate onset, coinciding with the moment of injury, may represent a severed nerve, while a delayed onset implies that the nerve is intact. In the latter case, it is the swelling or developing hematoma that causes the delayed paralysis. The prognosis is better if the patient has demonstrated some posttraumatic facial function, as this ensures that there is gross integrity of the nerve.

Fractures passing posterior to the labyrinth also may put the facial nerve at risk, as the fracture, while passing into the

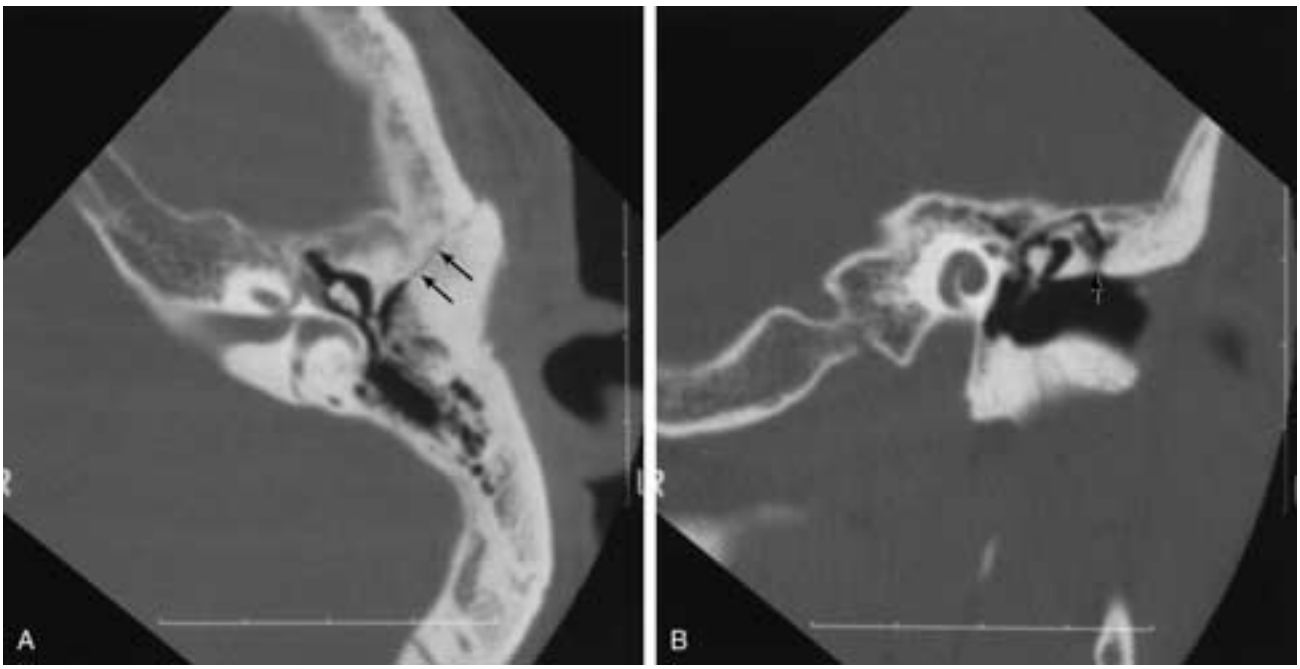

FIGURE 23-3 Longitudinal fracture. **A**, Axial CT image, left ear. Fracture line (*arrows*) is actually somewhat oblique to the long axis of the petrous bone. **B**, Coronal CT, left ear. Involvement of the EAC/tegmental air cell system (*arrow*).

jugular fossa or posterior wall of the temporal bone, usually passes through the vertical or mastoid portion of the facial nerve. These uncommon fractures are prone to transect the nerve.

Rarely, a fracture can pass both posterior and anterior to the otic capsule. The anterior fracture passes into the foramen lacerum and then can pass posteriorly along the petrooccipital synchondrosis to the posterior fossa. The posterior fracture enters the posterior fossa more laterally, in or near the jugular foramen, or perhaps through the posterior mastoid. This combination of fractures can result in a freely moving fragment including the otic capsule and petrous apex and has been referred to as a floating petrous bone.[17] The petrous apex can rotate slightly, putting pressure on or pinching the sixth nerve passing through Dorello's canal at the apex of the bone (Fig. 23-6). This can happen without injury to the eighth nerve, as no fracture line crosses its path. However, the posterior component of the fracture will likely cross the vertical facial nerve canal in the mastoid, causing facial paralysis.

Temporal bone fractures have little ability to form a ''callus.'' There is therefore a tendency for squamous invasion at the fracture site, and acquired cholesteatoma is a potential delayed complication[18, 19] (Fig. 23-5). These cholesteatomas have a tendency to become large and extensive, as most of these patients lack a history of chronic otitis media and therefore have well-pneumatized mastoids.

Longitudinal fractures are best diagnosed with CT. The MR imaging manifestations of this type of fracture include dural enhancement, believed to correlate with ''microfractures.''[20, 21]

Transverse Fractures

Transverse fractures are perpendicular to the long axis of the petrous pyramid and typically result from a blunt occipital or occipitomastoid impact[22–24] (Figs. 23-7 to 23-10). There are medial and lateral subtypes defined by their position relative to the arcuate eminence (a landmark along the superior petrous surface corresponding roughly to the position of the apex of the curve of the superior semicircular canal). The temporal bone's entry point for both fractures is usually near the vestibular aqueduct.[15, 16] The medial subtype of transverse fracture traverses the fundus (lateralmost aspect) of the internal auditory canal (IAC). Sensorineural hearing loss is secondary to cochlear nerve transection, and therefore is often complete and permanent. The lateral subtype of transverse fracture traverses the bony labyrinth rather than the IAC (Fig. 23-8). This results in sensorineural hearing loss, and there is frequently an associated perilymphatic fistula due to the communication between the middle ear and the inner ear as a result of the fracture.[25] Air can follow a fracture line from the middle ear into the labyrinth, causing a pneumolabyrinth. Carotid canal involvement is associated with catastrophic complications.[26]

Pseudofractures

Temporal bone pseudofractures can be subdivided into extrinsic sutures/fissures, intrinsic fissures, and intrinsic channels.[27]

Extrinsic sutures/fissures separate the temporal bone from adjacent bones. Examples include petrooccipital, temporooccipital, and occipitomastoid sutures.[27] The petrooccipital fissure, consistently appreciated between the clivus and the petrous apex, contains the inferior petrosal sinus coursing inferiorly from the cavernous sinus to exit the skull base via the anteromedial aspect of the jugular foramen (pars nervosa). The occipitomastoid suture is a constant structure visible on both axial and coronal CT images (Fig. 23-11). Its appearance varies from smooth and well corticated to irregular, coarse, and relatively wide. The observer should keep in

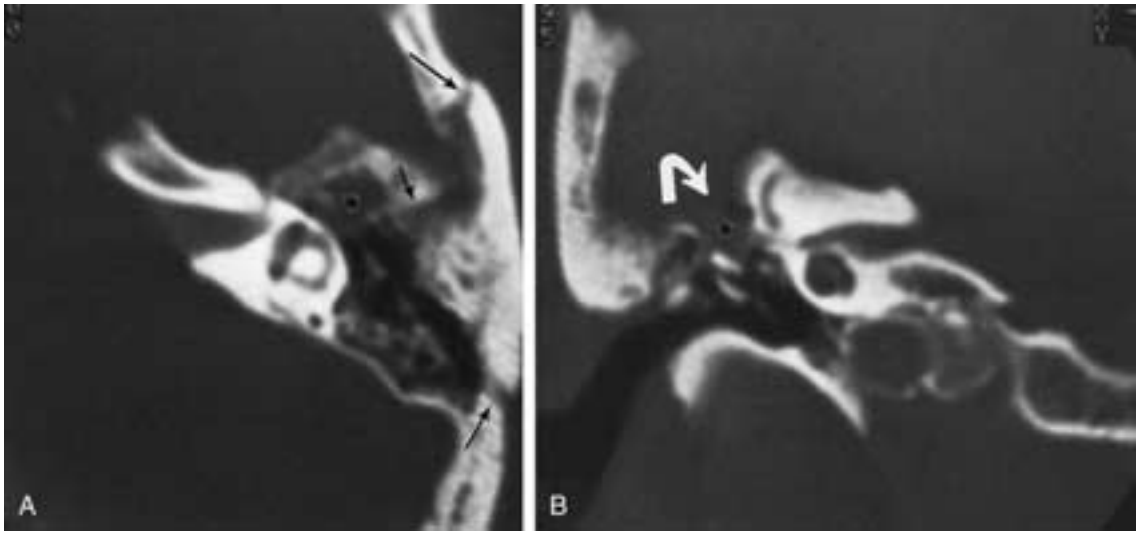

FIGURE 23-5 Complicated mixed fracture. **A**, Axial section. Fracture lines are demonstrated (*arrows*). A soft-tissue mass is identified in the attic (*). **B**, Coronal image. A large tegmen defect is present (*curved white arrow*). A soft-tissue mass is identified in the attic (*). This mass could represent encephalocele or cholesteatoma invading the fracture line. MR imaging was recommended.

FIGURE 23-6 Fracture dislocation of the temporal bone apex (floating petrous bone). CT. This child had a compression from laterally and presents with facial paralysis and sixth nerve palsy. **A**, Axial scan shows the fracture (*arrowheads*) crossing from the posterior plate of the mastoid anteriorly through the middle ear, exiting by the anterior genu of the facial nerve. The medial portion of the temporal bone (including the labyrinth) is a single movable fragment. This part of the bone has rotated slightly, impacting the tip against the clivus. This pinches into Dorrello's canal (*white arrow*), explaining the sixth nerve palsy. The fracture separates the mastoid segment (*black arrow*) of the facial nerve from the tympanic segment, explaining the facial paralysis. **B**, Coronal image shows the fracture line (*white arrowheads*) passing through the tegmen, then crossing the facial nerve into the middle ear. Note that the fracture separates the facial canal mastoid section (*black arrowhead*) from the tympanic section (*black arrow*).

mind that the transversely oriented sphenooccipital synchondrosis, consistently visualized on axial CT images, generally closes at approximately age 10.

The temporal bone has five parts: squamous, petrous, mastoid, tympanic, and styloid. Examples of intrinsic fissures include the tympanosquamous, tympanomastoid, and petrotympanic fissures. The tympanomastoid suture is longitudinally oriented along the posterior bony cortex of the EAC (Fig. 23-10). The tympanosquamous suture is typically oriented along the anterior surface of the EAC. EAC fractures cannot be consistently diagnosed unless the observer has a working knowledge of these normal variations. The petrotympanic fissure, containing the chorda tympani nerve and the anterior tympanic branch of the maxillary artery, is best seen on images obtained in the sagittal plane. The anterior tympanic spine forms the inferior boundary of this fissure and may be injured due to the retropulsive effects of chin-dashboard trauma.

There are numerous intrinsic channels. The cochlear aqueduct is a potential communication between the CSF in the pars nervosa of the jugular fossa and the perilymph of the basilar turn of the cochlea. In the coronal plane, the aqueduct is obliquely oriented, curving superiorly and tapering laterally toward the junction of the basilar turn of the cochlea and vestibule (Fig. 23-12). The aqueduct roughly parallels the long axis of the IAC. This is a consistently narrow channel identified on axial and coronal CT images. The vestibular aqueduct contains the endolymphatic duct and part of the endolymphatic sac. On axial images, the

FIGURE 23-7 Drawing of the transverse fracture. The fracture line is perpendicular to the long axis of the petrous bone. (From Swartz JD, Harnsberger HR. Imaging of the Temporal Bone, 3rd ed. New York: Thieme, 1998.)

FIGURE 23-8 Transverse fracture, lateral subtype. **A**, Axial CT image, right ear. Fracture (*arrows*) begins at the posterior petrous surface in the vicinity of the vestibular aqueduct and disrupts the anterior portion of the tegmen tympani, as well as the squamous portion of the petrous bone. **B**, Axial CT image, right ear, more inferior, also reveals disruption of the promontory fracture (*arrows*). Note the diffuse hematotympanum.

vestibular aqueduct is seen in cross section as an intrusion or channel into the posterior cortex of the petrous bone, oriented along the long axis of the petrous pyramid parallel to the posterior semicircular canal close to common crus of the labyrinth (Fig. 23-13). The vestibular aqueduct is obliquely oriented from superior to inferior and is therefore also well seen on sagittal imaging. The petromastoid (subarcuate) canal containing the subarcuate artery/vein is consistently seen at the petrous apex on axial CT images, appearing as a curvilinear lucency at the level of the superior semicircular canal passing between the anterior and posterior limbs of this canal (Fig. 23-14). The petromastoid canal is a remnant of the voluminous subarcuate fossa seen consistently in the newborn.[28]

The singular canal exits the posterior inferior part of the IAC and then runs parallel to the IAC to reach the labyrinth.[1] The singular canal contains the singular nerve, a branch of the inferior vestibular nerve supplying the posterior semicircular canal (Fig. 23-15). The mastoid canaliculus contains the nerve of Arnold, a branch of the vagus nerve, and can be seen in either the axial or coronal plane as a lucency connecting the jugular foramen with the mastoid segment of the facial nerve canal (Fig. 23-16). The inferior tympanic canaliculus (ITC) is oriented vertically and is consistently seen on coronal CT images between the carotid canal and the jugular fossa (Fig. 23-17). The ITC contains the inferior tympanic branch of the glossopharyngeal nerve, also known as the nerve of Jacobsen, and the

inferior tympanic artery. Interestingly, this is also the point of entry of the rare aberrant internal carotid artery, as the vertical portion of the carotid canal does not develop in this circumstance. This lucent channel should not be confused with a fracture.

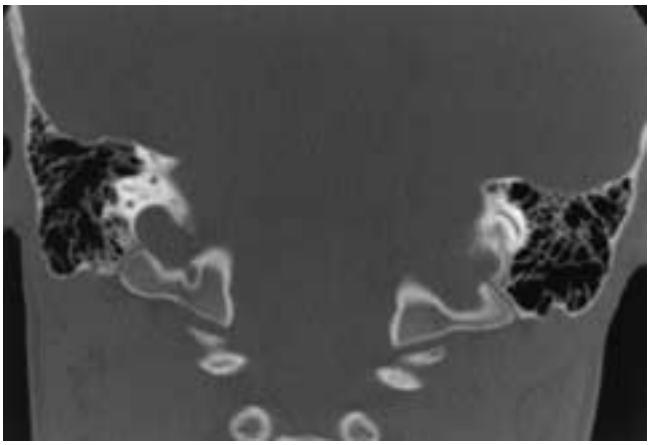

FIGURE 23-11 Pseudofracture, occipitomastoid sutures. This magnified coronal CT image of the left ear demonstrates normal occipitomastoid sutures (*arrows*). They are symmetric and smoothly corticated in this example, but may be irregular and asymmetric and still be within the range of normal.

OSSICULAR DISLOCATION AND FRACTURE

Ossicular injury can occur either in association with fractures of the temporal bone or as an isolated event. Longitudinal fractures are more commonly associated with ossicular dislocations than are transverse fractures, as the shearing force of a longitudinal fracture passes through the middle ear, putting the continuity of the ossicular chain at risk. Dislocations can occur without fracture and may result either from a penetrating injury or from blunt local trauma to the tympanic membrane. Blasts, which cause a rapid, wide pressure change in the EAC, can result in ossicular dislocation, as can a blow to the ear with a cupped hand.

In order to understand the pathophysiology of ossicular dislocation and posttraumatic conductive hearing loss, the

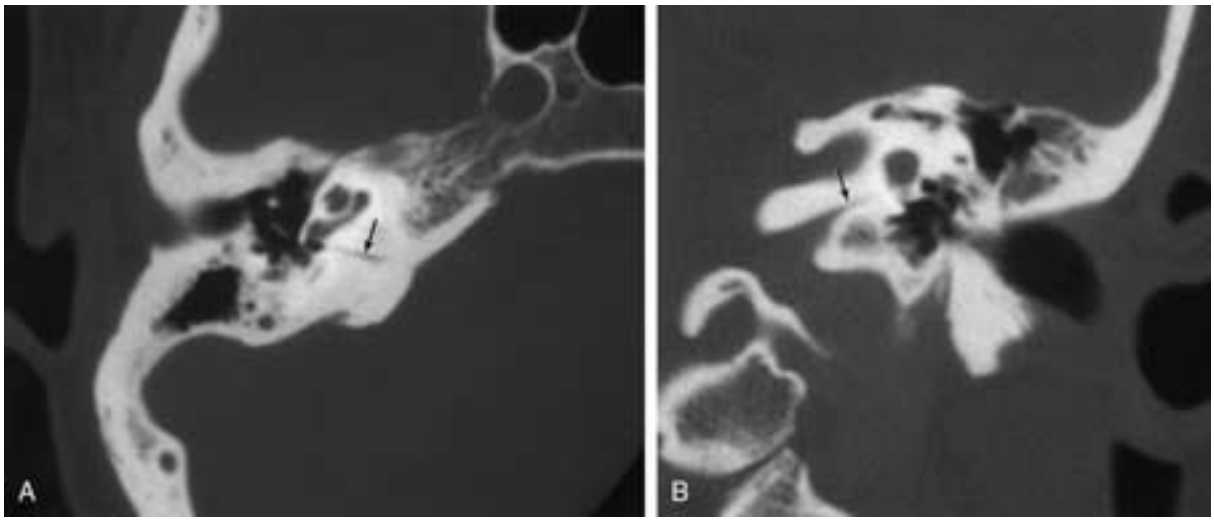

FIGURE 23-12 Pseudofracture, cochlear aqueduct. **A**, Axial CT image. **B**, Coronal CT image. These magnified CT images clearly demonstrate a normal-appearing cochlear aqueduct (*arrows*), which should not be confused with a fracture.

observer must appreciate the anatomy pertaining to the ossicular support[29] (Fig. 23-18). The malleus is well supported by the anterior, lateral, and superior malleal ligaments. In addition, both the short process and the manubrium are embedded within the tympanic membrane. The stapes is well supported by the stapediovestibular articulation (footplate/annular ligament) as well as by the

FIGURE 23-14 Pseudofracture, petromastoid canal. This is a magnified axial CT image of the left ear demonstrating a curvilinear lucency at the petrous apex (*arrow*) consistent with the petromastoid canal. (Modified from Swartz JD, Harnsberger HR. Imaging of the Temporal Bone, 3rd ed. New York: Thieme, 1998.)

ossicle, and most ossicular discontinuities involve the incus.[30]

The various types of ossicular discontinuity include incudostapedial subluxation, malleoincudal subluxation, incus dislocation, stapes fracture and dislocation, and the rare malleus fracture.[31–34] Dislocation of the entire malleoincudal complex has also been reported.

The incudostapedial joint is a fragile enarthrosis. A well-accepted theory for the cause of incudostapedial subluxation is tetanic contraction of the tensor tympani and stapedius tendons that results in a medial thrust of the incus and a posterior thrust of the stapes.[2, 34] Most observers believe this to be the most common variety of posttraumatic ossicular disruption. In order to diagnose such a disruption, a sound knowledge of the normal anatomy is needed. This anatomy is best appreciated on axial images. The lenticular process of the incus is well seen in the axial plane, as is the stapes superstructure, including the stapes head (capitulum) and the anterior and posterior crura. The footplate is seen as a thin cortical bony line crossing the oval window. The supporting stapedius tendon is also appreciated in this plane emanating from the pyramidal eminence of the posterior tympanum. More anteriorly lies the tensor tendon attaching to the malleus neck. Incudostapedial subluxation may be manifest by either an anterior or a posterior position of the lenticular process relative to the stapes head (Figs. 23-19 and 23-20).

The malleoincudal articulation is a true diarthrodial joint well protected within the attic (epitympanic recess). This joint has a capsule as well as medial and lateral ligamentous support.[35] The pathophysiology of malleoincudal subluxation is similar to that of the incudostapedial joint subluxation. These are also best seen on axial images as separation of the malleus head from the incus body (the ice cream from the cone) (Figs. 23-21 and 23-22).

The diagnosis of incus dislocation requires demonstration of complete separation of the incus from its incudosta-

pedial and the malleoincudal attachments.[32] This may be partial or complete. If the incus dislocation is complete, the incus may reside in the attic, middle ear, or EAC, or may be completely absent, presumably resorbed over time (Figs. 23-23 and 23-24). The diagnosis is best made using axial CT images; however, coronal CT images may demonstrates the incus lateral to the malleus, referred to as a Y configuration[30] (Fig. 23-23).

VIEW IMAGE

FIGURE 23-21 Malleoincudal articulation, normal anatomy. This is a magnified axial CT image of the left ear demonstrating the normal ice cream cone within the attic, with the malleus anteriorly (*arrow*) and the incus posteriorly.

Stapes arch fractures are believed to be due to twisting torsion of the incus, while stapes footplate fractures are often associated with the lateral subtype of transverse fracture.[36] Stapes dislocation into the vestibule is often the result of overaggressive use of cotton-tipped cleansing devices[36, 37] (Fig. 23-25). The normal stapes superstructure should be visible in the axial plane in every patient, provided that appropriate technique is utilized. The diagnosis of stapes injury is more difficult than the diagnosis of most of the other varieties of ossicular injury, but it should be suspected if the stapes is not visualized in the axial plane in the appropriate clinical context. Recall that there is an association of stapes fractures with perilymphatic fistula.

COMPLICATIONS OF TEMPORAL BONE TRAUMA

Clinical complications associated with temporal bone fractures include fistulous communications, vertigo, hearing loss and facial nerve dysfunction.

Fistulous Communications

Fistulous communications include CSF leak and perilymphatic fistula.[38, 39] Traumatic CSF leak is usually secondary

to disruption of the tegmen tympani or roof of the middle ear. Because endochondral bone heals by fibrous union, there is an increased likelihood of CSF leak due to a fracture in this location.[38] If there is a CSF leak and there is also disruption of the tympanic membrane, there will be CSF *otorrhea*. If there is an intact tympanic membrane, the CSF drains via the eustachian tube into the nasopharynx and nasal cavity, resulting in CSF *rhinorrhea*. CSF leaks may resolve spontaneously, but surgical intervention is required when the leak persists for more than 7 to 10 days due to the risk of developing meningitis.[3] Larger tegmen defects may result in a meningoencephalocele[40–42] (Fig. 23-26).

Perilymphatic fistula is an abnormal communication between the inner ear perilymph and the middle ear space.[42–45] Classic corresponding clinical symptoms include fluctuating sensorineural hearing loss, tinnitus, vertigo, and possibly nystagmus. Although nystagmus may be either neoplastic or idiopathic in origin, trauma is the most

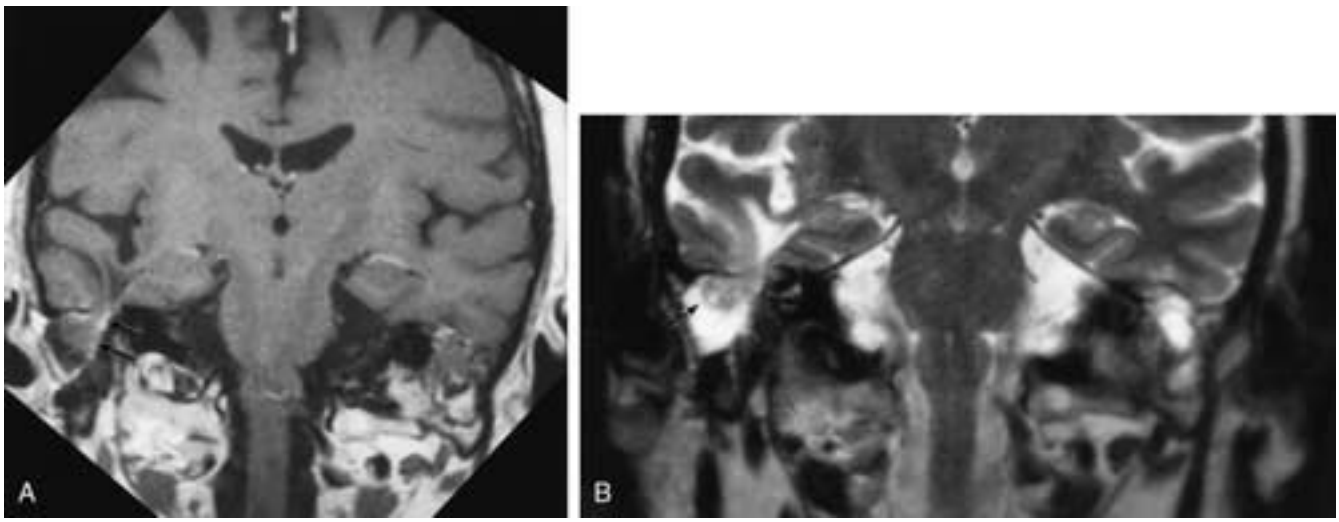

FIGURE 23-26 Posttraumatic meningoencephalocele. **A**, Coronal T1-weighted postcontrast image. **B**, Coronal T2-weighted fast spin-echo image. There is tegmen disruption on the right side. common cause. Perilymphatic fistula can be associated with congenital inner ear anomalies. The etiology of perilymphatic fistula may be a sudden increase in CSF pressure transmitted to the perilymph, the so-called *explosive* etiology, or tympanic membrane trauma, the so-called *implosive* etiology. The oval window and round window are the most common sites of perilymphatic fistula. Sudden gross movement of the tympanic membrane is transmitted, via the ossicular chain, to the stapes, which may be dislodged, and pronounced pressure changes may tear the round window membrane. In some centers, suspected perilymphatic fistula is an indication for surgical exploration and repair.

The imaging diagnosis of perilymphatic fistula may be quite elusive. The diagnosis can be suggested in the presence of labyrinthine fracture, stapes fracture/nonvisualization of the stapes, unexplained middle ear effusion, or pneumolabyrinth[46–48] (Fig. 23-27). The symptoms of perilymphatic fistula overlap with those of Meniere's disease, another elusive imaging diagnosis.[49]

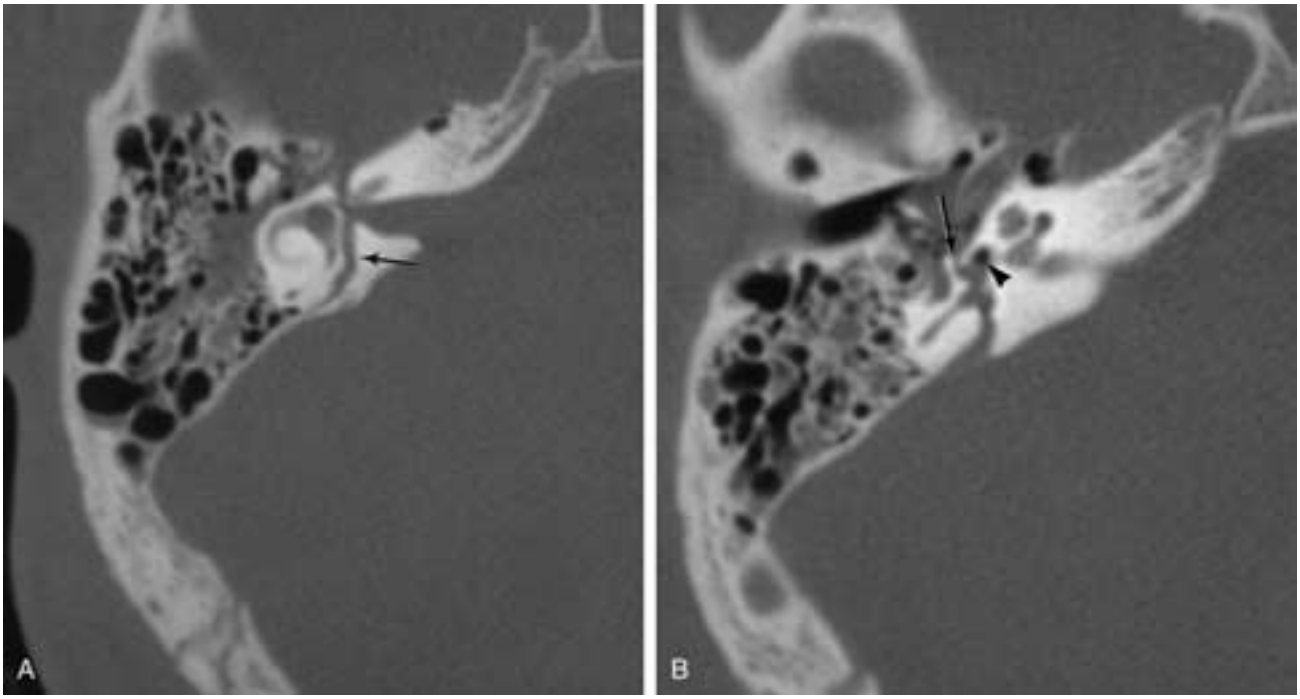
Hearing Loss

Posttraumatic hearing loss may be sensorineural or conductive. Sensorineural hearing loss can be caused by fracture through the IAC, by fracture through the labyrinth, and by the so-called cochlear concussion, which is a disruption of the membranous labyrinth, typically without imaging manifestations.[4, 6, 23] Sensorineural hearing loss can also be caused by intralabyrinthine hemorrhage, brainstem injury (specifically to the cochlear nuclei or inferior colliculi), and perilymphatic fistula (Fig. 23-27). Shearing injury at the root entry zone of the vestibulocochlear nerve has been reported on numerous occasions, and impaction of the tentorium against the tectum secondary to acceleration-deceleration forces is the presumed cause of damage to the inferior colliculi in this context. Intralabyrinthine hemorrhage can occur secondary to blunt trauma or result from a coagulopathy or sickle cell disease.[50] This is best appreciated on axial T1-weighted noncontrast thin-section images[51] (Fig. 23-28).

Conductive hearing loss is common in this context and is particularly interesting to evaluate with CT due to the high incidence of important positive findings. Causes include hemotympanum, tympanic membrane damage, and ossicular discontinuity (see above). A conductive hearing loss that persists after blood is resorbed and the tympanic membrane is healed/repaired is presumably due to ossicular damage.[35–37, 52] Ossicular injuries are far more commonly the result of longitudinal rather than transverse fracture and, as mentioned, there are numerous reports of ossicular injury resulting from the aggressive use of cotton-tipped ear-cleansing devices.

Facial Nerve Dysfunction

Excluding Bell's palsy, trauma is the most common cause of facial nerve dysfunction.[53–55] Possible etiologies



VIEW IMAGE

include intraneuronal hematoma, impingement by fracture fragments, and complete transection. Complete transection may result in complete, permanent facial palsy. Surgical intervention is a controversial topic but appears more valuable when the palsy is of delayed onset, as the etiology is more likely edema, swelling, or hematoma rather than complete transection. Delayed-onset paralysis is more common than that of immediate onset. When indicated, surgical decompression is generally most helpful if performed within 72 hours of onset of facial nerve dysfunction, prior to the development of Wallerian degeneration.[3, 53]

As indicated previously, facial nerve compromise is more common with transverse than with longitudinal fractures. The medial subtype (see above) is especially notorious in this regard, as the path of the fracture line extends through the region of the junction of the labyrinthine segment of the nerve canal with the fundus of the IAC. This region is considered to be the most vulnerable segment of the nerve by most observers. The lateral subtype of transverse fracture typically disrupts the nerve at the first genu. In a recent series, facial nerve injury was noted in 48% of fractures involving the otic capsule and in 10% to 18% of fractures sparing the otic capsule.[2] Facial paralysis associated with longitudinal fracture occurs less commonly (10% to 20%) and is often delayed, and the involvement is usually within the proximal tympanic segment of the nerve. Hematoma can affect the midtympanic segment of the nerve near the oval window, and spontaneous resolution of the facial paralysis is the rule in this circumstance. There is a general consensus that facial nerve injury is much less common in pediatric patients.[41]

MR imaging may play a crucial role in the evaluation of the traumatized facial nerve, as pathologic enhancement of the nerve may occur secondary to disruption of the blood-nerve barrier. This finding correlates especially well with traction and stretching of the greater superficial petrosal nerve leading to hematoma, edema, and nerve degeneration.[19] Demonstration of hematoma formation requires the use of thin-section noncontrast T_1-weighted images.

Various diseases and dysplasias can affect the temporal bone and impair audiovestibular function. Some, such as otosclerosis, involve only the temporal bone, while others are more generalized, involving the temporal bone as well as other portions of the skeletal system. Some conditions cause demineralization of the otic capsule, and these are frequently genetically determined.[1–3] Both ears are often affected, and the impact on the quality of life can be devastating.[1] Patients with these lesions may present with conductive, sensorineural, or mixed hearing loss, depending on the location and extent of the lesions. Dysplastic bone can compress nerves, resulting in cranial neuropathies, or can limit ossicular chain movement. Because high-resolution computed tomography (CT) can depict very subtle bone findings, it is the modality of choice for evaluating osseous changes in the temporal bone. Magnetic resonance (MR) imaging can be used to evaluate the lumen of the labyrinth and the bone marrow, but depicting definitive bone changes is often difficult. However, contrast-enhanced MR imaging can help predict the vascularity or activity of certain lesions.

OTOSCLEROSIS

Otosclerosis is a disorder of the bony labyrinth and stapes affecting only humans.[1] It has an autosomal dominant inheritance with varying degrees of expressivity.[4] This slowly progressive disorder has a 65% to 72.5% female predominance, with a peak incidence in the second or third decade.[1, 5–8] The disease is bilateral in 80% of patients, and although tinnitus may be the presenting symptom, hearing loss will always develop. Although a conductive component is almost always present, there may be a sensorineural or mixed hearing loss.[5, 9]

The temporal bone is unique in that there normally is persistence of primary endochondral bone as the middle

Copyright © 2003, Mosby, Inc. All rights reserved.

layer of the cochlear or otic capsule. This middle layer is between the thin inner endosteal layer (bordering the lumen of the labyrinth) and the outer periosteal layer. Resorption of this middle endochondral layer, with deposition of spongy vascular new bone, is referred to as otosclerosis or otospongiosis.[8, 10, 11] This abnormal bone is usually less dense than the surrounding normal bone, but it can be sclerotic, presumably representing a mature or inactive form of otosclerosis. Imaging studies can confirm the clinical assumption of otosclerosis and can play a role in excluding some of the other causes of hearing loss.[11] In this regard, high-resolution CT is the modality of choice for evaluating the labyrinthine windows, stapes footplate, cochlear capsule, and other inner ear structures.[11–14] (Figs. 24-1 and 24-2).

The lesions of otosclerosis may be isolated to the oval window or may involve the labyrinth more extensively. The terminology used to refer to this disease is variable, with some otologists simply referring to otosclerosis and then subclassifying it depending on the type of hearing loss present. Other otologists refer to either fenestral or retrofenestral (cochlear) otosclerosis.[1–14] The fenestral type refers to lesions involving only the oval window region, while the retrofenestral type refers to otosclerosis that more extensively affects the cochlea. The retrofenestral type seldom occurs without a fenestral component.

Oval Window Involvement (Fenestral)

Radiologic evaluation may not be necessary in patients who present with a conductive hearing loss and disease limited to the oval window (fenestral otosclerosis).[15, 16] The clinical findings are quite characteristic, as patients present with a progressive conductive loss, a normal tympanic membrane, and no evidence of middle ear inflammation. Seen through the tympanic membrane, the promontory may have a faint pink tinge reflecting the vascularity of the lesion. This coloration has been referred to as the Schwartze sign. Some patients with a sensorineural hearing loss require imaging to confirm the diagnosis of retrofenestral otosclerosis or to exclude retrocochlear lesions.[16–18] A conductive hearing loss is almost always secondary to impingement of abnormal bone on the stapes footplate, and it is this oval window involvement that is the basis of the name fenestral otosclerosis. The most common lesion of otosclerosis occurs

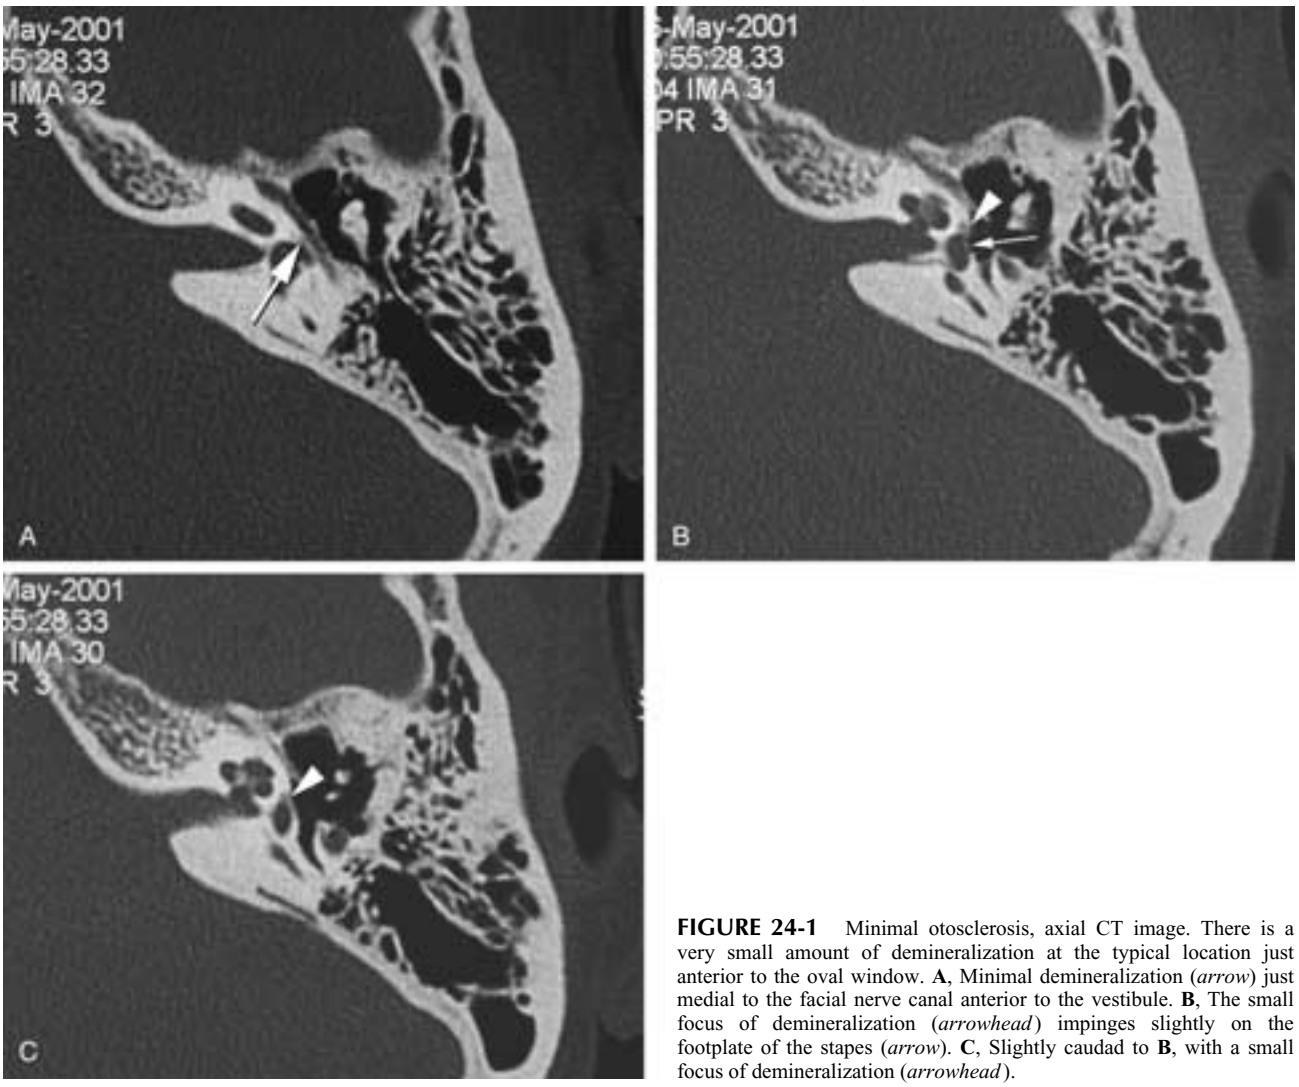

FIGURE 24-1 Minimal otosclerosis, axial CT image. Note the area of demineralization (*arrowhead*) just medial to the cochlea. **B**, Coronal image shows the demineralized bone (*arrow*). This slice is just anterior to the oval window.

in the bone just anterior to the oval window, at the location of the embryologic fissula ante fenestram[9–11, 19] (Figs. 24-1 to 24-3). The fissula is a thin fold of connective tissue extending through the endochondral layer, approximately between the oval window and the cochleariform process, where the tensor tympani tendon turns laterally toward the malleus. To diagnose fenestral otosclerosis with CT, assessment of patients with a noninflammatory conductive hearing loss must include careful evaluation of the oval window for either subtle lucent areas or otosclerotic foci.[20, 21] This is best accomplished by using high-resolution CT with a 1-mm (or less) slice thickness. Early disease is visualized as a small, demineralized focus anterior to the oval window (Fig. 24-1). This represents the abnormal ''spongiotic'' bone replacing the normal dense otic capsule, and this imaging finding confirms the diagnosis. Other foci of demineralization should be sought in both ears, as the incidence of bilateral involvement is high even when the audiogram shows no measurable air-bone gap in the other ear. With more pronounced disease, the demineralized bone enlarges, protrudes slightly into the middle ear cavity, and further impinges on the anterior margin of the oval window (Fig. 24-2). CT may demonstrate narrowing of the oval window, thickening of the footplate of the stapes, and small decreased density lesions in the lateral wall of the labyrinth. Rarely, the lesion is dense, approaching the same density as

The bone has approximately the same density as the otic capsule.

the otic capsule (Fig. 24-4). In these circumstances, the disease is identified by showing thickening of the bone at the anterior margin of the oval window. This may reflect the later, inactive phase of otosclerosis.[8]

Complete obliteration of the oval window, obliterative fenestral otosclerosis, occurs in approximately 2% of cases and is classified into three types: (1) massive thickening of the footplate that almost fills the oval window niche; (2) massive overgrowth of the margins of the oval window, obliterating the niche and obscuring the footplate; and (3) a combination of footplate thickening and marginal overgrowth.[5, 8, 22] Occasionally, patients have only subtle thickening of the stapes footplate/annular ligament complex. This appearance may also occur as a result of previous inflammatory disease with the development of tympanosclerosis.[23]

When an oval window lesion is not appreciated on imaging, the ossicular chain must be carefully evaluated for evidence of a congenital anomaly or perhaps for an indication of an inflammatory cause of the conductive hearing loss. On occasion, although no abnormality is apparent despite an intensive imaging evaluation, at surgery congenital stapes fixation may be identified.[10]

Careful evaluation of the round window, facial nerve canal, jugular foramen, and cochlear aqueduct is necessary as part of the preoperative imaging assessment.[21] Round window obliteration secondary to otosclerosis is rare, occurring with retrofenestral disease (Figs. 24-5 and 24-6). If this occurs, stapes surgery is less likely to be successful and hearing improvement will be minimal.[22] A small percentage of patients with fenestral otosclerosis also have lateral ossicular fixation, usually manifested by a bony web interposed between the malleus or incus and the lateral attic wall. Dehiscence of the facial nerve may also be appreciated on CT, and the preoperative demonstration of this anomaly can help the surgeon avoid facial nerve injury.[8, 24]

Treatment of the fenestral component of otosclerosis is surgical, and various procedures have been designed to reestablish the conductive pathway from middle to inner ear. The stapes is either removed or a hole is drilled through the footplate and a prosthesis inserted (Figs. 24-7 and 24-8). Other procedures have included stapes mobilization and fenestration of the horizontal semicircular canal.[25] Currently, the most common procedure involves drilling a small hole in the stapes (stapedotomy), with the placement of a small-diameter Teflon-wire piston through this small fenestra in the footplate (Fig. 24-9). This procedure has lessened complications including postoperative vertigo, granuloma formation, and fibrous fixation of the lenticular process to the promontory.[22] CT is useful to evaluate the precise location of the prosthesis and to assess postoperative complications.[25, 26] It should be noted that because of volume averaging effects, a thin wire prosthesis may not be

visualized, whereas thicker pistons may appear wider than their actual size.[11]

With oval window manipulation, a pouring, jet-like outflow (gusher) or milder welling-like flow (oozer) of cerebrospinal fluid (CSF) may occur in patients with a defect either in the modiolus or in the bone at the fundus of the internal auditory canal, giving a communication between the CSF and the perilymph.[22] Some authors have suggested a communicating pathway through an enlarged cochlear aqueduct; however, there is considerable controversy in the otolaryngologic literature on this subject. Enlargement or flaring of the cochlear duct aperture seen on imaging is of very doubtful significance.[27]

Cochlear Otosclerosis (Retrofenestral)

Cochlear (retrofenestral or labyrinthine) otosclerosis presents with combined sensorineural and conductive hearing loss. Isolated sensorineural loss is considered to be extremely rare. A few patients present with vestibular symptoms.[28–30] The cause of the sensorineural hearing loss

in otosclerosis is controversial, and cytotoxic enzymes have been implicated.[31, 32] Diffusion of these enzymes into the cochlear fluid is theorized to be responsible for hyalinization of the spiral ligament and subsequent hearing loss.

The basilar membrane forms the boundary between the cochlear duct and the scala tympani, and this membrane thickens as it approaches the apical turn. Low-frequency tones have a maximum effective amplitude toward the apical turn, while high-frequency tones have a maximum effective amplitude at the basilar turn, where the basilar membrane is relatively thin. Areas of demineralization at various locations within the cochlear capsule can be appreciated on CT, and attempts have been made to correlate the type of frequency loss in sensorineural hearing loss with the location of demineralized foci seen on CT.[33, 34]

In cochlear or retrofenestral otosclerosis, demineralization of the cochlear capsule is greater than that seen in fenestral otosclerosis, and the area just anterior to the oval window is almost always involved. In addition, the so-called double ring or fourth turn sign refers to a low-density demineralized enchondral defect around the cochlea[11, 12, 33–35] (Figs. 24-6 and 24-9). These lucent lesions of cochlear otosclerosis may abut the lumen of the labyrinth or may be separated from it by denser bone. These areas of demineralization represent otospongiosis in the cochlear capsule (Figs. 24-10 and 24-11). In the chronic or sclerotic phase of the disease, these lesions can undergo remineralization and become indistinguishable from the normal dense cochlear capsule. In this case, there may be no CT manifestations other than subtle periosteal thickening, and this may explain the relatively high incidence of otherwise asymptomatic sensorineural hearing loss occurring in young patients with normal CT scans.[11, 12]

There is a strong tendency for the findings in cochlear

otosclerosis to be symmetric, and CT scans obtained in both the axial and coronal planes should be carefully evaluated for otospongiotic foci. CT densitometry has been proposed as an objective method of assessing otospongiosic foci, and this technique may provide an opportunity to monitor the effectiveness of therapy before and after medical treatment.[36, 37]

MR imaging has had limited applications for evaluation of the cochlear capsule. The normal cochlear or otic capsule is seen as a complete loss of signal because of its dense bony structure. Both T1- and T2-weighted images may show very subtle signal changes in a demineralized cochlear capsule, but the T2-weighted images are considered relatively less sensitive.[15, 16, 35] On the other hand, in the assessment of the membranous labyrinth prior to cochlear implant surgery in patients with profound bilateral hearing loss, T2-weighted imaging is very useful. The fluid of the membranous labyrinth gives high signal on T2-weighted images, and obliteration of the signal indicates fibrosis or bone deposition within the labyrinthine lumen.[15, 18, 35]

Contrast-enhanced T1-weighted imaging is presumed to give information concerning activity of the lesions, as linear enhancement is noted in the bony labyrinth in the active phase of the disease. Enhancement is presumed to be due to contrast medium pooling in the numerous blood vessels of the otospongiotic foci[11, 15, 16, 35, 38] (Fig. 24-12).

Retrofenestral or cochlear otosclerosis has been considered a relative contraindication to cochlear implant surgery.[10, 18, 33, 34, 39–41] However, end-stage otosclerosis and profound sensorineural hearing loss may still be managed with multichannel cochlear implantation. Temporal bone histopathology studies indicate relatively good spiral ganglion populations, and these patients are frequently cited as ''good responders'' after cochlear implantation[42–44] (Fig. 24-13). Preoperative CT and MR imaging evaluation for assessment of the intracochlear space is necessary.[18, 44, 45]

VIEW IMAGE

Postoperative evaluation of cochlear implants can be performed with CT; however, assessment of the insertion depth of the device can also be achieved with plain films[10, 46] (Fig. 24-13).

Differential Diagnosis

The differential diagnosis of fenestral otosclerosis is quite limited, while that of cochlear (retrofenestral) otosclerosis includes various diseases that demineralize the cochlear capsule. Such diseases include osteogenesis imperfecta and Paget's disease. Ankylosing rheumatoid arthritis and inflammatory/infectious diseases such as syphilis have also been mentioned as mimicking some aspects of otosclerosis.[8, 10, 28] These diseases have systemic manifestations, in contrast to otosclerosis. Diffuse labyrinthine ossification, labyrinthitis ossificans, is a different entity and is not considered a consequence of otosclerosis unless inflammation complicates stapes surgery[47] (Fig. 24-14). Ossification of the membranous labyrinth may occur as a result of a previous inflammatory process such as meningitis, blood-borne septic emboli, middle ear infection, trauma, or surgery such as labyrinthectomy.[8, 47] Labyrinthine ossification may be localized and limited to the basilar turn of the cochlea or the round window niche, and such a limited manifestation is usually of a tympanogenic etiology.[10]

FIBROUS DYSPLASIA

Fibrous dysplasia is a disorder of unknown etiology characterized by slowly progressive replacement of normal bone by dysplastic fibroosseous tissue. The ability to form normal mature lamellar bone is defective, resulting in a developmental arrest at the level of immature woven bone. The abnormal trabeculae of woven bone form a disordered whorled pattern and spicules of bone undergo resorption and reformation, with active but disordered osteoblastic activity. The replaced tissue may be relatively acellular, with predominance of collagenous ground substance, or it may be extremely cellular. There may be a whorled arrangement resembling that of osteogenic sarcoma, and scattered islands of cartilage may be present.[1, 48, 49]

This proliferative process may give rise to expansion, distortion, and structural weakness of the bone. Because fibrous dysplasia primarily involves the cancellous bone and rarely involves the cortical bone, this lesion usually widens the bone by replacing the normal medullary space. The abnormal dysplastic bone is often covered by a thin normal cortical margin.[8, 48–51] Females are affected twice as often as males.

Fibrous dysplasia may affect one, a few, or many bones and can be grossly divided into monostotic, oligostotic, and polyostotic forms. The polyostotic lesions tend to be distributed unilaterally. The monostotic form may arrest at

Copyright © 2003, Mosby, Inc. All rights reserved.

puberty, whereas the polyostotic form may progress beyond the third and even later decades. The McCune-Albright syndrome is a special form of polyostotic fibrous dysplasia, representing about 3% of the cases, and is associated with endocrine disorders.[48, 49] Malignant transformation of fibrous dysplasia is rare (0.5%), and although several forms of sarcoma may develop, osteosarcoma is the most common.[48, 52]

The radiologic findings of fibrous dysplasia can be grossly divided into three patterns: pagetoid, sclerotic, and cyst-like. Throughout the entire skeletal system the pagetoid form of fibrous dysplasia is most common, occurring in about 53% of cases; the patient is usually over 30 years of age. The pagetoid form has regions of bony expansion and mixed areas of radiopacity and radiolucency (Fig. 24-15). The sclerotic form, which occurs in 23% of cases, is usually seen in younger patients and consists radiographically of more homogeneous ''ground-glass'' opacities and bone expansion (Figs. 24-16 and 24-17). The cyst-like form, which occurs in 21% of cases, also occurs in younger patients and is characterized by round or oval ''cystic'' lesions with sclerotic borders. In some cases, the sclerotic and cyst-like forms are precursors of the pagetoid form. In the temporal bone, fibrous dysplasia is almost always of the predominantly sclerotic form, and the cyst-like form is uncommon.[50, 53]

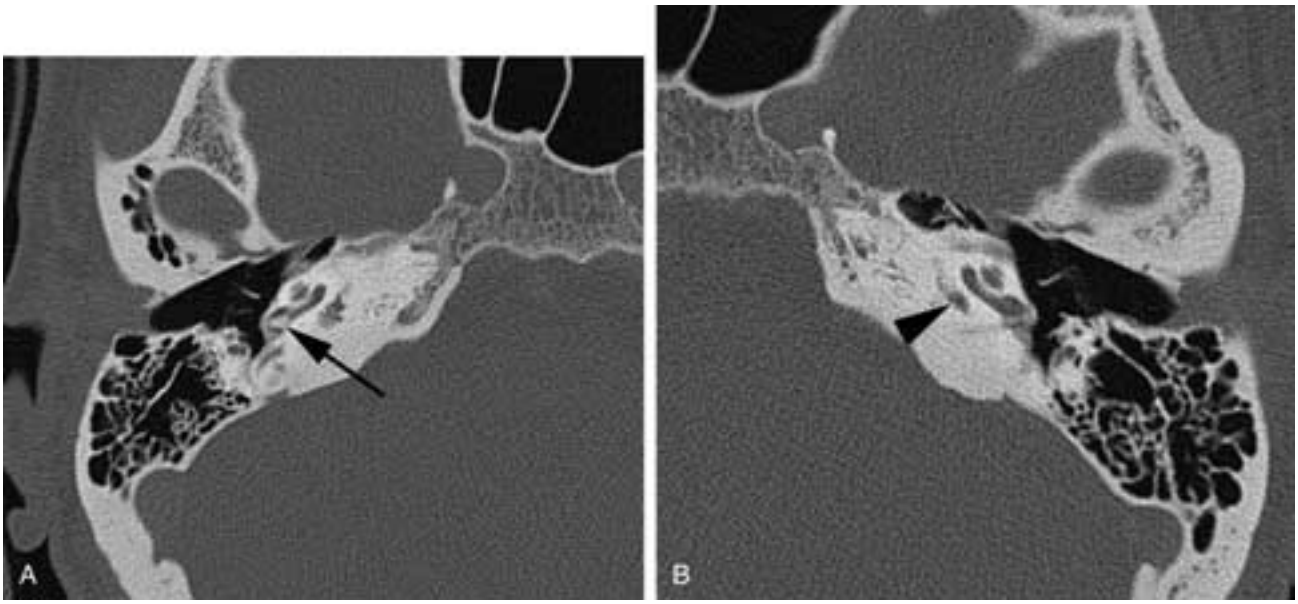
The most common presenting symptoms relating to fibrous dysplasia in the temporal bone are progressive hearing loss (characteristically conductive), an increase in the size of the temporal bone or a postauricular deformity, and obstruction of the external auditory canal (Fig. 24-15C). Stenosis or obstruction of the external auditory canal may result in infection and lead to external canal cholesteatoma and keratosis obturans medial to the narrowing.[50, 54, 55] Facial weakness or hearing loss, or both, may occur as a result of entrapment and compression of the seventh and eighth cranial nerves.[55–57]

High-resolution CT of the temporal bone depicts details of the lesions of fibrous dysplasia. The most common CT findings include an increase in bone thickness, a homogeneous radiodensity, and a loss of the trabecular pattern.[50] There may be varying degrees of obliteration of the mastoid air cells and external auditory canal. Primary involvement of the tympanic cavity is relatively uncommon. Secondary pathology such as cholesteatoma with erosion of the canal and ossicles is shown superimposed on the primary pathology.[55] Bony impingement on the internal auditory canal or facial nerve may explain the corresponding symptoms. The cochlear capsule may be involved, though it is characteristically spared.[50, 53, 56, 57]

Although CT demonstrates lesions of fibrous dysplasia best, MR imaging also can depict the abnormalities. On both T1- and T2-weighted images, low to intermediate signal intensity is usually seen in the largest part of the lesions. Smaller regions of high signal intensity perhaps representing cysts may be also observed. Following administration of contrast material, the lesions demonstrate moderate to marked enhancement (Fig. 24-18). The cellularity and activity of the lesions do not correlate well with signal intensity and enhancement degree or pattern.[58] MR imaging is also useful for evaluating the cranial nerves, including the seventh and eighth, the brainstem, and other soft tissue structures adjacent to the lesions.[56]

Differential Diagnosis

The differential diagnosis of fibrous dysplasia of the temporal bone includes other *benign fibroosseous lesions*



VIEW IMAGE

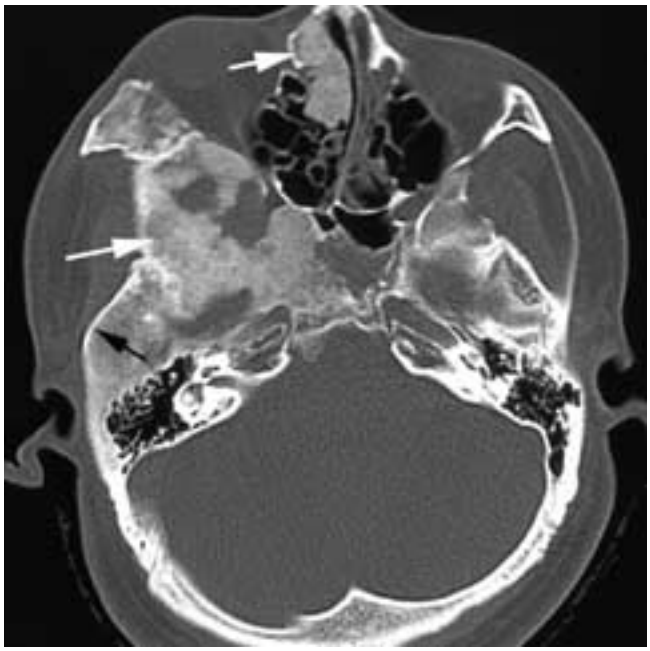
such as *ossifying fibroma*. The imaging findings of these lesions are very similar, but ossifying fibroma tends to be more localized, appearing as more of a mass-like lesion. However, it is often impossible to differentiate by imaging alone, and the histopathologic findings of these two lesions are also quite similar. *Paget's disease* is one of the major differential diagnoses of temporal bone fibrous dysplasia. It is usually bilateral and exhibits osteopenia with a small number of sclerotic foci, and the patients are usually older than those with fibrous dysplasia.[59, 60] In Paget's disease, there usually is not the same degree of osseous thickening seen with fibrous dysplasia, and the outer margin of the otic capsule is more frequently demineralized. *Hyperparathyroidism* may also cause ground-glass, sclerotic bone, particularly with the secondary form of this disease. Usually, the skeletal manifestations are symmetrically evident throughout the entire skeletal system, and there is systemic hypercalcemia.[61, 62] *Sclerosteosis* (*endosteal hyperostosis*) is an autosomal recessive disease first appearing in infancy or early childhood. There is overgrowth of the skull, vertebrae, and mandible, with gigantism and syndactyly. Cranial nerve palsies are common. The long bones have sclerotic changes, which can be differentiated from those of fibrous dysplasia.[63, 64] *Neurofibromatosis* may simulate fibrous dysplasia, particularly when a neurofibroma erodes into or originates within the temporal bone. However, the additional clinical features and other skeletal manifestations are different from those of fibrous dysplasia. *Chondroblastoma* is rare in the temporal bone. However, it can present as an expansile soft-tissue density mass with bony erosion and may simulate fibrous dysplasia. Spotty calcification may be seen, and the lesion enhances with contrast material.[65, 66] An

Copyright © 2003, Mosby, Inc. All rights reserved.

aneurysmal bone cyst may occur in the temporal bone. Although this cyst is expansile, it is usually accompanied by pain and tenderness, symptoms uncommonly associated with fibrous dysplasia.[8, 48, 57, 67–69] *Chondrosarcoma* may mimic the pagetoid form of fibrous dysplasia, with spotty calcification often being seen on CT and arc-like or curvilinear enhancement often being seen on contrast-enhanced MR[70, 71] (Fig. 24-19). *Metastatic bone tumors* may present a sclerotic, almost ground-glass appearance and may simulate fibrous dysplasia or other benign fibroosseous lesions, particularly metastases from prostate or breast cancers.

PAGET'S DISEASE (OSTEITIS DEFORMANS)

A well-known English surgeon, Sir James Paget (1877, 1882), described the clinical and pathologic features of this disease, although it was Czerny (1873) who named this disorder osteitis deformans.[1, 60] Paget's disease is quite common, affecting 3% of the population over 40 years of age and up to 10% of patients over 80 years of age. There is an ill-defined genetic factor suggested by familial and geographic clustering. The disease is a chronic, sometimes progressive condition that may present as a solitary monostotic form that remains asymptomatic, only to be discovered as an incidental finding. Alternatively, the disease may develop into a clinically apparent entity. In its disseminated polyostotic form, many bones in different regions are affected, with the pelvis being most commonly involved, followed by the femur, skull, tibia, and spine. Progressive involvement of the temporal bone results in an increase in size and changes in the architecture and position of the petrous pyramid, external auditory canal, middle ear, and otic capsule.[59, 60, 72, 73] The ossicles are rarely involved in the pagetic process.[1]



VIEW IMAGE

FIGURE 24-16 Fibrous dysplasia. Axial CT image demonstrates diffusely increased ground-glass density (*white arrows*). Note the involvement of the sphenoid bone. There is also involvement of parts of the ethmoid bone anteriorly. Note that the cortex (*black arrow*) is intact.

The histopathology of Paget's disease in the temporal bone can be divided into four phases: (1) osteolytic, (2) mixed, (3) osteoblastic, and (4) remodeled phases.[1] The osteolytic phase begins with increased vascularity and cellularity in the adjacent bone marrow spaces. Osteoclastic resorption of trabeculae of the spongiosa or walls of the Haversian canals of the compacta can be seen. Heightened bone formation leads to an increase in vascularity, with blood flow as much as 20 times that of normal.[1] In the calvarium, the outer cortical table becomes thin and may even disappear. This results in *osteoporosis circumscripta*, sharply demarcated areas of ''washed-out'' radiolucency, which are typically seen in the skull base or calvarium[8, 72] (Fig. 24-20).

Eventually, the osteolytic areas may be replaced by new bone. This process is associated with an increase in bone density and thickness and represents the mixed phase, with new bone formation predominating over bone resorption. A mixture of phases results in a ''cotton-wool'' appearance caused by simultaneous osteolysis, and sclerosis and a prominent mosaic pattern is seen. A ''burn-out'' or osteoblastic phase follows. The involved bone is replaced by densely packed, narrow trabeculae of lamellar, coarse-fibered bone. The medullary cavity may be filled by avascular, fibrous connective tissue. This sclerotic form of the disease is much less common in the temporal bone. A pagetoid lesion in the sclerotic phase has an ''ivory'' appearance, which distinguishes it from the adjacent bone. Bone expansion continues until resorption occurs. Although the mass of the bone is increased, it is structurally unstable and weak, probably because of the failure of the collagen fibers to align along stress lines in each spicule of bone.[1] Like other normal bones, the inactive osteoblastic pagetic bone may undergo remodeling into normal-appearing lamellar bone with distinct Haversian canals. Malignant transformation is seen in about 1% of patients.[1, 8, 59, 72, 74]

Hearing impairment is the most common manifestation in patients with the temporal bone involvement of this disease. The loss may be conductive, sensorineural, or mixed. Less common symptoms include tinnitus, vertigo, and unsteadiness.[59, 72, 74] High-resolution CT of the temporal bone shows the decreased density typically seen when demineralization is progressing. Areas may show a mixed appearance of bone thickening and sclerosis[60, 75, 76] (Figs. 24-21 to 24-23).

In the temporal bone, the disease begins at the petrous apex, the site of the greatest marrow deposition, and progresses inferolaterally. Demineralization of the otic capsule may occur as a later manifestation. Areas of resorption tend to advance from the periphery of the otic capsule toward the central regions. The stapedial footplate may be thickened, contributing to hearing loss. The mastoid process may show bone thickening, demineralization, or a mosaic pattern.[73] Frequently, the central skull base is also involved. With progression, basilar invagination occurs and the petrous apex tilts upward as the softening bone responds to the various forces placed on the skull base and the cervical spine protrudes into the foramen magnum (Fig. 24-22). Hearing impairment, from direct involvement of the temporal bone, may be further accentuated by stretching of

FIGURE 24-17 Fibrous dysplasia demonstrating a mixed appearance of pagetoid and sclerotic, ground-glass forms of fibrous dysplasia in the left temporal bone. The cochlear capsule is spared. **A**, Diffuse involvement of the petrous apex (*black arrow*). Note that the cortex is partially defined (*white arrow*). Some chondroid matrix (*arrowhead*) is noted in the region of the sphenoid. **B**, There is enlargement of the bone. The lateral wall of the attic (*arrowhead*) impinges slightly on the head of the malleus. **C**, Coronal image shows the ground-glass appearance (*black arrow*) and the intact cortex (*white arrow*) characteristic of fibrous dysplasia. **D**, There is some demineralization of the peripheral portion of the otic capsule, with subtle demineralization (*arrowhead*) of the superior semicircular canal.

the eighth cranial nerve that results from the basilar invagination.[8]

MR findings of Paget's disease are variable. Marrow replacement by fibrous tissue results in decreased signal intensity on T1-weighted images; however, patchy, heterogeneous high signal intensities may occur secondary to hemorrhage or slow flow in vascular channels. Contrast enhancement reflects the hypervascular nature of this process.[77] Diffuse meningeal enhancement may be noted, presumably reflecting increased metabolism and blood flow of the lesions (Fig. 24-21).

Differential Diagnosis

The variety of findings in Paget's disease leads to an extensive differential diagnosis. *Fibrous dysplasia* results in widening of the diploic spaces as the medullary region becomes filled with fibrous material. Often there is a ground-glass appearance, and the corticomedullary junction tends to be preserved. Patients with fibrous dysplasia are usually younger and have greater marrow involvement than patients with Paget's disease.[76] The manifestations of *hyperparathyroidism* are usually seen throughout the skele-

ton and may be accompanied by other clinical and or laboratory manifestations. Hyperparathyroidism may cause diffusely sclerotic bone changes, particularly secondary hyperparathyroidism and renal osteodystrophy. A progressive form of osteitis fibrosa cystica, osteofibrosis associated with localized cysts, rarefied and thinned cortex, distorted and blurred cancellous trabeculae, and deformity can be observed.[61, 62] *Osteogenesis imperfecta* may have some similarities to the findings in Paget's disease, but the clinical and radiologic findings are different. *Hereditary hyperphosphatasia* (juvenile Paget's disease) is a rare autosomal recessive disease seen in infancy and childhood. It is characterized by generalized cortical thickening and sustained elevation of serum alkaline phosphatase and urinary hydroxyprolamine. Thickening and deossification of the skull base with bowing of tubular bones are observed.[67, 68, 78] *Progressive diaphyseal dysplasia* (Camurati-Engelmann-Ribbing disease or syndrome) is an autosomal dominant disease usually diagnosed in childhood. It consists of typical hyperostosis of the long bones that can be easily differentiated from Paget's disease.[68, 79] The skull base thickening and sclerosis seen in *pyknodysostosis* is also

uniformly present throughout the skeleton, unlike the patchy lesions of Paget's disease.[80] *Meningiomas* are usually sharply demarcated and tend to show inward growth from the inner table of the skull, which differentiate them from Paget's disease.[8, 69] *Metastatic osseous lesions* may also mimic Paget's disease, particularly when originating from prostate or breast cancers. Clinical information is important to differentiate these diseases.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (Van der Hoeve's syndrome) is a genetic disorder of connective tissue caused by an error in type I collagen formation manifested as a deficiency in fibroblastic and osteoblastic activity.[1, 81] The classic description of osteogenesis imperfecta includes fragile bones, blue sclerae, and deafness. The fragile bones lead to recurring fractures and skeletal deformity. Additional clinical manifestations are abnormal dentinogenesis, hyperextensible joints, and wormian bones. The genetic defects leave patients with decreased amounts of type I collagen, and this form of collagen is not only predominant in bones but is also present in skin, connective tissue, and dentin.[67, 82]

Four major types of osteogenesis imperfecta have been described with several subtypes, based on relatively distinct syndromes that reflect different defects in type I collagen synthesis.[83–85] Type I, previously called osteogenesis imperfecta tarda, is the most common and mildest form and reflects decreased production of type I collagen. Patients usually present with a bone fracture following minimal or no trauma. Blue sclerae are always present, and deafness is common after childhood. These patients can have joint dislocations and hyperflexibility, as well as easy bruisability. Dentin production may be normal or abnormal. Type II, previously known as osteogenesis imperfecta congenita, is the most severe form of this disease. Death in utero or shortly after birth is common due to multiple fractures of the skull, vertebrae, or chest wall. Type III osteogenesis imperfecta presents with marked bony deformity and frequent early fractures of the long bones. Short stature is common, as is abnormal production of dentin or *dentinogen-*

Copyright © 2003, Mosby, Inc. All rights reserved.

esis imperfecta. The sclerae originally are blue but turn white as the patient grows. The genetic defect is not well understood. Type IV osteogenesis imperfecta has variable severity, with a defect in one subunit of collagen. Some patients exhibit normal sclera and dentin with minimal bone fragility.[67, 84, 85]

Radiologic findings of the skull include generalized osteopenia with diminished trabeculae and a thin cortex and wormian bones; occasionally, basilar invagination is noted. The extremities show marked bowing and deformity as a result of multiple fractures. The ribs are thin and notched and may also show evidence of fractures. The vertebrae are usually biconvex because the soft endplates mold around the intervertebral disk, and sclerosis of the vertebral bodies may occur.[75, 84, 85]

CT of the temporal bone may show proliferation of undermineralized, thickened bone around the otic capsule (Fig. 24-24). As this thickened bone extends from the labyrinth, the middle ear cavity may be narrowed; the oval window may become obstructed, with the stapedial crura embedded in a dysplastic osseous mass; and the facial canal may be narrowed, with corresponding damage to the facial nerve.[75, 76, 86, 87] The CT appearance is very similar to that of retrofenestral or cochlear otosclerosis but is much more extensive. In osteogenesis imperfecta, the demineralization can reach the level of the superior semicircular canal.

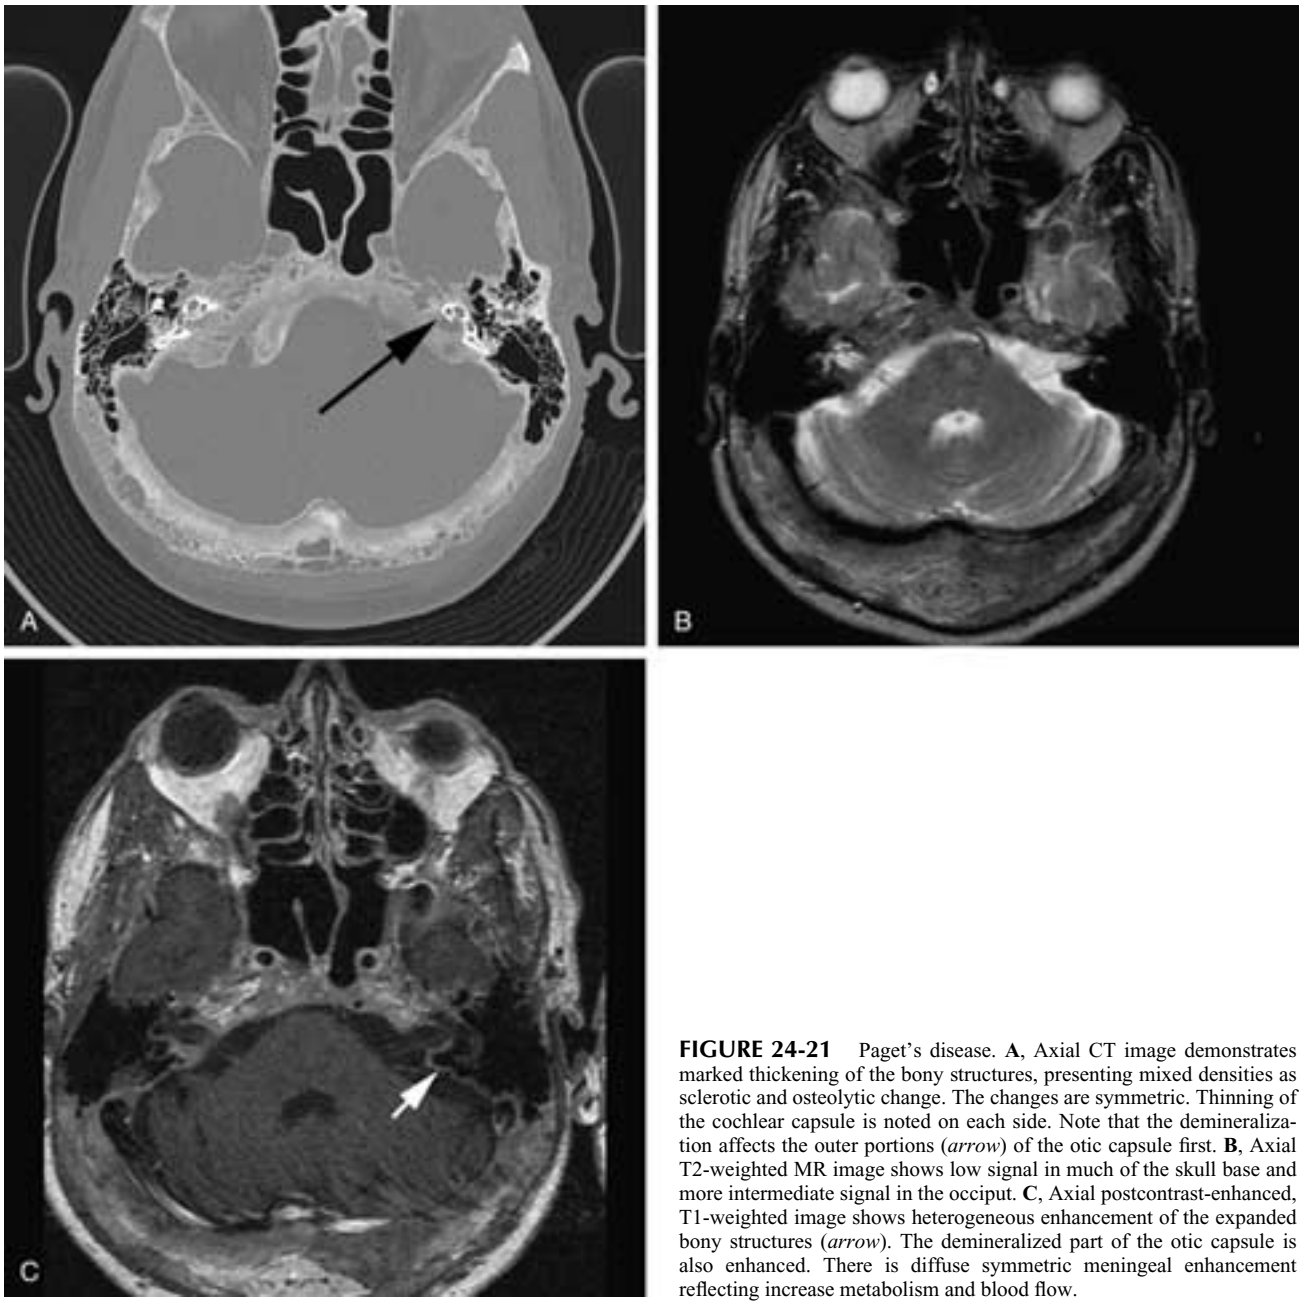

FIGURE 24-21 Paget's disease. **A**, Axial CT image demonstrates marked thickening of the bony structures, presenting mixed densities as sclerotic and osteolytic change. The changes are symmetric. Thinning of the cochlear capsule is noted on each side. Note that the demineralization affects the outer portions (*arrow*) of the otic capsule first. **B**, Axial T2-weighted MR image shows low signal in much of the skull base and more intermediate signal in the occiput. **C**, Axial postcontrast-enhanced, T1-weighted image shows heterogeneous enhancement of the expanded bony structures (*arrow*). The demineralized part of the otic capsule is also enhanced. There is diffuse symmetric meningeal enhancement reflecting increase metabolism and blood flow.

The histologic appearance of these two disorders is very similar.[1]

Differential Diagnosis

The differential diagnosis of osteogenesis imperfecta includes *otosclerosis* (Fig. 24-25), *Paget's disease*, and *hyperparathyroidism*. Retrofenestral or cochlear otosclerosis causes a zone of decreased density around the otic capsule similar to that of osteogenesis imperfecta. Also, otosclerosis can have focal areas of sclerosis, and the abnormal bone may involve the stapedial footplate and oval window. It is virtually impossible to differentiate otosclerosis from osteogenesis imperfecta in some cases, but usually the extensive nature of osteogenesis imperfecta will suggest the diagnosis. Obliteration of the oval and round windows and sensorineural hearing loss may be encountered and may

compromise the success of stapedial surgery.[87] Typically, patients with Paget's disease are older and do not have prominent hypertrophic bone around the stapes and oval window. Usually, the manifestations of hyperparathyroidism are seen throughout the skeletal system. These patients have cortical bone cysts, with local tenderness and systemic hypercalcemia. Hyperparathyroidism may also cause sclerotic bone changes, particularly with the secondary form of this disease.[61, 62, 75]

OSTEOPETROSIS

Osteopetrosis (Albers-Schonberg disease) is a rare hereditary disorder in which there is a defect in the mechanism of bone remodeling. Failure of osteoclastic function is the most likely etiology, along with defective absorption of the primary spongiosa. This results in thick, dense, but fragile bones giving rise to the suitable terminology *chalk bones* and *marble bone disease*.[1, 2, 10, 88–90] Overproduction of immature bone causes thickening of the cortex and narrowing or obliteration of the medullary cavity, and may cause neutropenia and anemia.[88–90]

There are two modes of inheritance in osteopetrosis: autosomal recessive (malignant) and autosomal dominant (benign). There may be severe and mild forms of the less common autosomal recessive type.[91] There is frequent stillbirth, and those surviving birth rarely survive childhood. The clinical features may be severe, as compromise of the marrow cavity, obliterated by the immature bone, can lead to pancytopenia and extramedullary hematopoiesis. There may be multiple cranial nerve palsies due to foraminal stenosis. Hydrocephalus, hepatosplenomegaly, improper dental development, and deafness may also be present.[88]

The autosomal dominant type of osteopetrosis is separated into type I and type II, both of which may be asymptomatic. Type I patients may experience bone pain or have symptoms of foraminal stenosis. These patients may have normal fracture rates. Type II patients often have long bone fractures with minimal trauma and may show delayed healing. There is an intermediate recessive type that is less severe than the typical autosomal recessive type in its manifestations of anemia, hepatosplenomegaly, and frequent fractures. An autosomal recessive type with renal tubular acidosis has also been described. Affected patients have renal tubular acidosis, cerebral calcifications, hypotonia, mental retardation, and easy fracturing that improves with increasing age.[67, 87, 92]

The radiographic findings differ among the various types of osteopetrosis. The autosomal recessive form shows generalized dense bone and flaring of the metaphyses from defective tubular modeling. Transverse striations are often seen as a result of alternating areas of mature and sclerotic bone.[67] In the autosomal dominant type I disease, sclerosis of the skull is pronounced and thickening of the cranial vault is evident, without involvement of the spine. The long bone may have ''Erlenmeyer flask'' deformity of the metaphyseal region from overproduction and faulty resorption of bone.[93] Autosomal dominant type II disease shows endplate thickening of the vertebrae resulting in a ''rugger jersey'' appearance of the spine. The base of the skull shows sclerosis, but the calvarium has little involvement[94–96] (Fig. 24-26). The intermediate recessive type gives rise to marked thickening and sclerosis of the base of the skull. The autosomal recessive type with renal tubular acidosis demonstrates intracranial calcifications, most commonly centered in the basal ganglia. Metaphyseal expansion and endobones (bone within bone) may also be present.[67]

In patients with the autosomal recessive form of osteopetrosis, temporal bone CT shows increased mastoid density and a lack of pneumatization of the mastoid air cells, which may be filled with osteoporotic bone (Fig. 24-27). The internal auditory canals are shortened and trumpet-shaped. The subarcuate fossae are enlarged, resulting in a fetal appearance of the bone that persists past infancy. The ossicles may be thickened and enlarged.[91, 97] MR imaging shows obliteration of the mastoid and generalized thickening of the bone (Figs. 24-26 and 24-28).

Differential Diagnosis

When diagnosing osteopetrosis, it is important to consider inheritance, age of manifestation, and radiologic findings in the skeletal system. Paget's disease is characterized by recurrent bone resorption and formation. The temporal bone characteristically shows bony resorption, with occasional sclerosis of specific portions. The age and systemic manifestations of Paget's disease differ from those of osteopetrosis. Fibrous dysplasia is a disorder of proliferating fibroosseous tissues that results in widening of the diploic spaces. Patients with fibrous dysplasia have greater marrow involvement than patients with osteopetrosis. Hyperparathyroidism may also cause sclerotic bone changes, particularly with the secondary form.[62] It can be differentiated from osteopetrosis by clinical information or laboratory tests. Pyknodysostosis is an autosomal recessive disease first evident in infancy and early childhood and

Copyright © 2003, Mosby, Inc. All rights reserved.

characterized by short stature, frequent fractures, and a large cranium with frontal and occipital bossing. Thickening of the base of the skull with sclerosis is often seen. Osteosclerosis in patients with pyknodysostosis is uniform, and the long bones retain their normal external shape, unlike the autosomal recessive type of osteopetrosis.[80] Sclerosteosis (endosteal hyperostosis) is a rare, potentially lethal, autosomal recessive disorder with characteristic facial and skeletal features. Overgrowth of the skull, vertebrae, and mandible with giantism and syndactyly are noted. The temporal bone changes include a marked increase in overall size and extensive sclerosis. Cranial nerve palsies are common in this condition because of attenuation of their bony canals.[63, 64, 67, 98] Progressive diaphyseal dysplasia (Camurati-Engelmann-Ribbing syndrome) is an autosomal dominant disease usually diagnosed in childhood. It is characterized by muscle weakness, bone pain, and difficulty in walking. The unusual hyperostosis of the long bones in progressive diaphyseal dysplasia gives a thick, irregular cortex rather than the more uniformly dense bone seen with osteopetrosis.[67, 68, 78–80] Osteopathia striata (Voorhoeve syndrome) is an autosomal dominant disease, that may result in generalized temporal bone sclerosis and conductive hearing loss.[99]

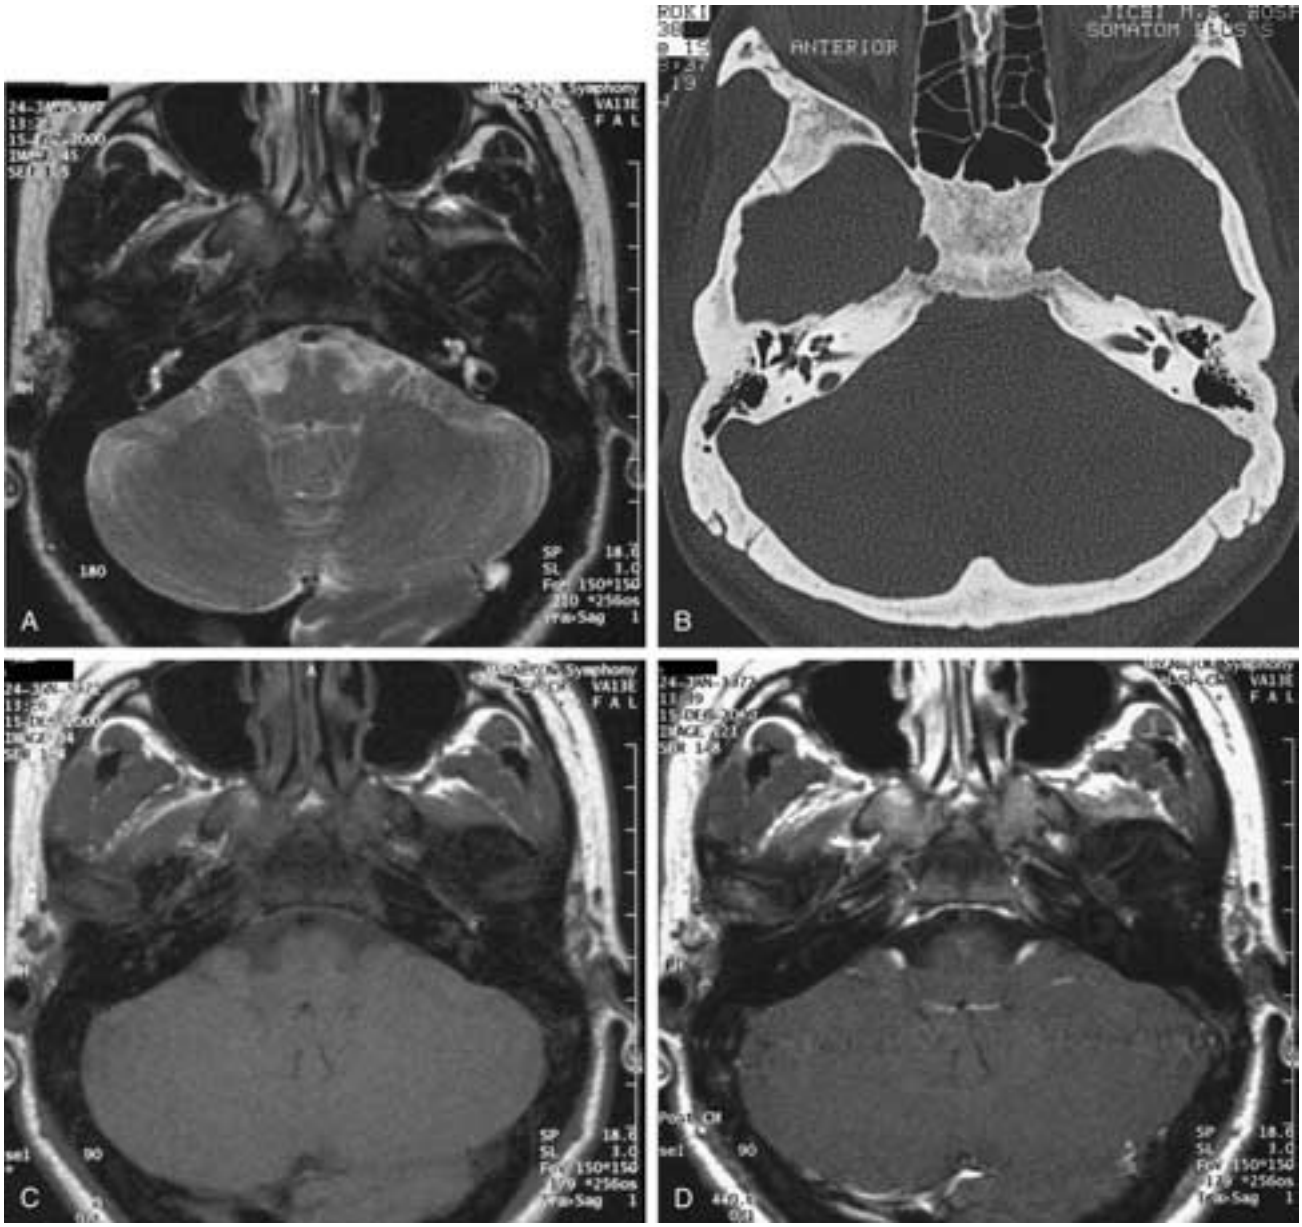

FIGURE 24-26 Osteopetrosis. **A**, Axial CT image demonstrates diffuse sclerotic change in the skull base including the temporal bone. **B**, Axial T1-weighted MR image shows absence of the high signal usually seen in the normal fatty marrow of the skull base. **C**, Axial T2-weighted MR image shows diffuse low signal from the skull base. The normal high signal of the membranous labyrinth is preserved. **D**, Axial postcontrast-enhanced, T1-weighted image shows minimal enhancement of the residual marrow in the clivus.

PROGRESSIVE DIAPHYSEAL DYSPLASIA (CAMURATI-ENGELMANN-RIBBING SYNDROME)

Progressive diaphyseal dysplasia (Camurati-Engelmann-Ribbing syndrome) is a rare autosomal dominant disease initially described in 1922 by Camurati.[100] This was followed by a similar report by Engelmann in 1929.[101] Neuhauser and his colleagues named this disease progressive diaphyseal dysplasia in 1948.[102] Patients with this disorder are usually diagnosed in childhood and show a variety of symptoms such as headache, poor appetite, muscle weakness, bone pain, easy fatigability, difficulty in walking, and exophthalmos. Vestibular nerve dysfunction may rarely occur.[103] This disease represents a slowly progressive and unpredictable hyperostotic process characterized by new bone formation along both the periosteal and endosteal surfaces of the long bones. The calvarium and other membranous bones are commonly affected in severe cases.[67, 68, 76, 78, 79, 87]

The radiologic findings in this disease are usually symmetric, with the upper extremities less often affected than the lower extremities. In mild cases there is only minimal middiaphyseal thickening of the cortex. Patients

Copyright © 2003, Mosby, Inc. All rights reserved.

with more advanced conditions exhibit more pronounced sclerosis that has spread to the metaphyseal regions, with narrowing of the medullary cavities. In some severe cases, both the skull base and calvarium show the characteristic sclerosis, and the vertebral column, shoulder girdles, and metacarpal and metatarsal bones can also be affected.

The CT examination documents mild to moderate thickening of the skull base with hyperostosis and sclerosis. The middle ear may be completely encased by sclerotic bone, along with widespread foraminal narrowing (Figs. 24-29 and 24-30; see also Fig. 12-103). MR imaging of the skull base shows a signal void around the base of the skull and calvaria on both the T1-weighted and T2-weighted images. Hyperostotic bone may be seen encasing the otic capsule, middle ear, and external ear.[67, 68, 104–106]

The diagnosis of progressive diaphyseal dysplasia should be established as early as possible, since treatment determines the severity and progression of the disease. Treatment options include alternate-day administration of corticosteroids, which may yield significant relief of pain and symptoms. Calcitonin injections have also been shown to relieve symptoms. Surgery may be indicated to relieve pain and decompress the affected cranial nerves.[79, 103, 104, 106]

Differential Diagnosis

The differential diagnosis of progressive diaphyseal dysplasia includes various rare diseases involving sclerotic changes in the temporal bone: generalized cortical hyperostosis (van Buchem's disease), sclerosteosis (endosteal hyperostosis), craniotubular sclerosis, craniometaphyseal dysplasia, craniodiaphyeal dysplasia, pyknodystosis, osteopetrosis, and Paget's disease.[8, 102]

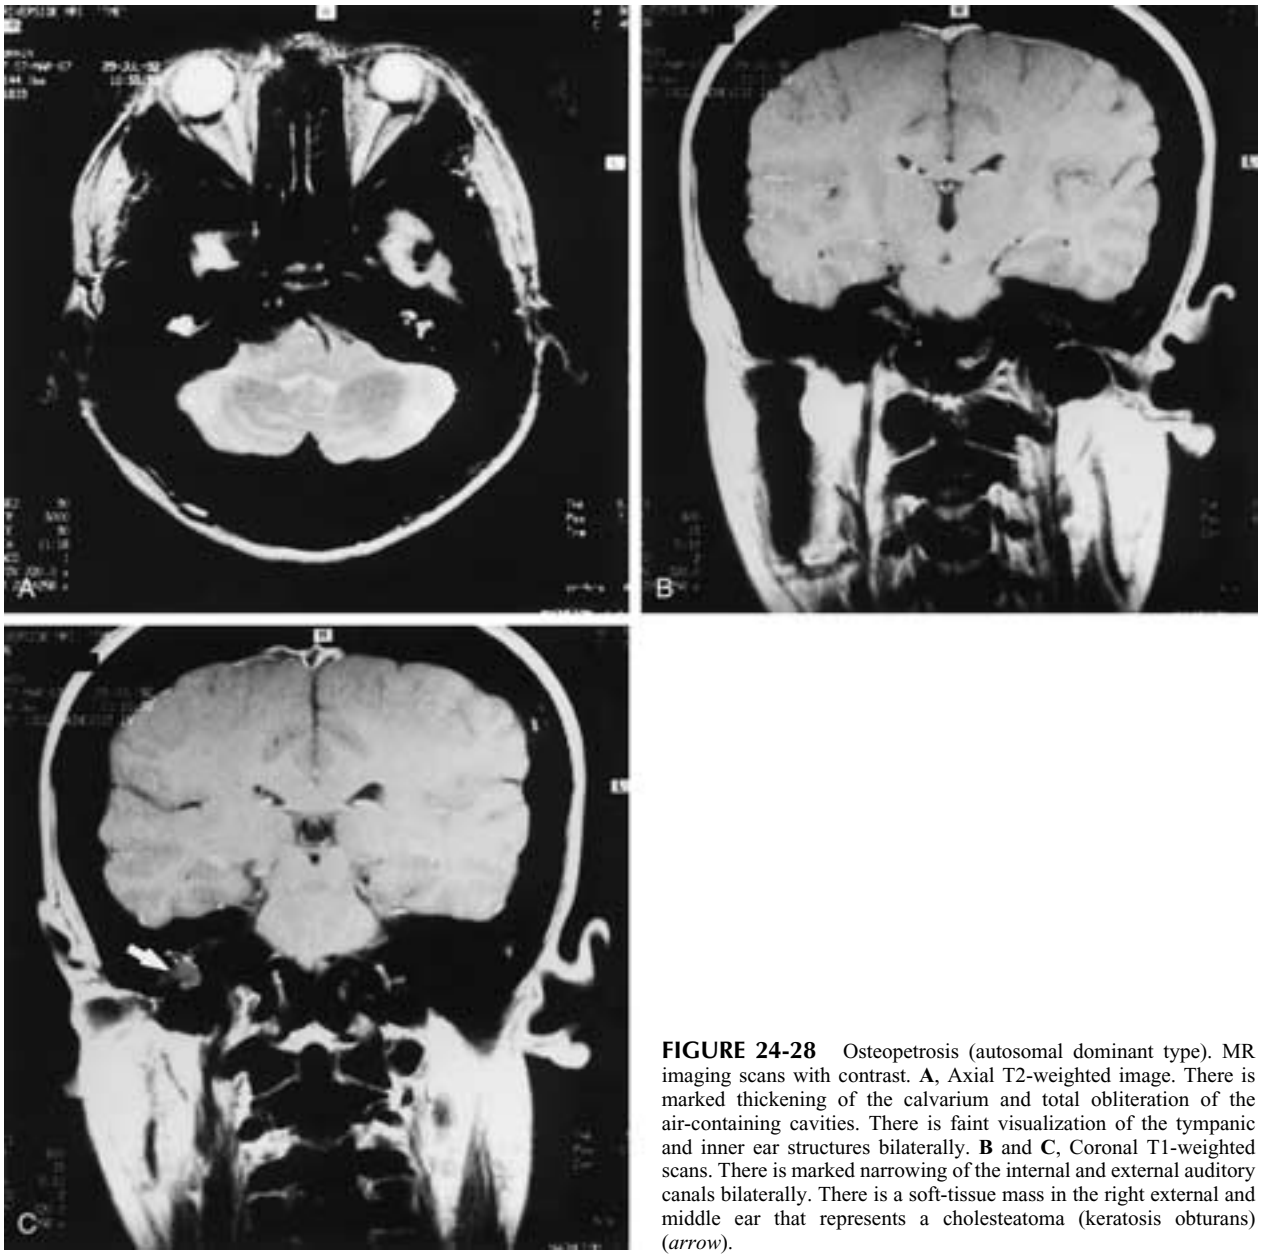

FIGURE 24-28 Osteopetrosis (autosomal dominant type). MR imaging scans with contrast. **A**, Axial T2-weighted image. There is marked thickening of the calvarium and total obliteration of the air-containing cavities. There is faint visualization of the tympanic and inner ear structures bilaterally. **B** and **C**, Coronal T1-weighted scans. There is marked narrowing of the internal and external auditory canals bilaterally. There is a soft-tissue mass in the right external and middle ear that represents a cholesteatoma (keratosis obturans) (*arrow*).

FIGURE 24-29 Progressive diaphyseal dysplasia (Engelmann's disease). Remarkable bony density involving the entire cranial base, including the temporal bones, is demonstrated. (From Swartz JD, Harnsberger HR. Imaging of the Temporal Bone. New York: Thieme, 1992.)

OTHER DYSPLASIAS AND DISORDERS CAUSING OSTEOSCLEROSIS OF THE TEMPORAL BONE

Other entities of dysplasias or diseases present diffusely or focally increased density lesions with or without cystic or decreased densities in the temporal bone. When diagnosing diseases described before in this chapter, such diseases must be considered as their differential diagnoses. Many have overlapping imaging findings in the skull base. The distribution of the abnormality in the peripheral skeleton is frequently more characteristic and is helpful in separating these various rare entities.

Endosteal Hyperostosis

Generalized Cortical Hyperostosis (van Buchem's Disease) is an autosomal recessive form of endosteal hyperostosis. It is characterized by osteosclerosis of the skull base and calvarium, mandible, and long and short bones (Fig. 24-31). Enlargement of the mandible is first noted in childhood, usually at puberty. Signs and symptoms of van Buchem's disease become apparent earlier than in the autosomal dominant form of endosteal hyperostosis, *Worth's syndrome*.[67] Narrowing of the neural foramina and neurologic impairment can occur in patients with both autosomal recessive and dominant forms of endosteal hyperostosis, and an elevated level of alkaline phosphatase is typically present.[107–109] Other types of autosomal dominant endosteal hyperostosis have been reported, showing unusual manifestations of sclerosis of the jaw bones but sparing the mandibular ramus.[110]

Sclerosteosis is a rare, potentially lethal, very severe form of endosteal hyperostosis with autosomal recessive inheritance. The disease begins in infancy or early childhood, causing overgrowth of the skull, vertebrae, and mandible with giantism and syndactyly. The temporal bone changes include a marked increase in overall size, extensive sclerosis, narrowing of the external auditory canal, and severe constriction of the internal auditory canal, fallopian canal, eustachian tube, and middle ear cleft. Cranial nerve palsies are common in this condition because of attenuation of their bony canals. Reduction in the size of the internal carotid artery, and severe obliteration of the sigmoid sinus and jugular bulb, also occur. Loss of hearing, generally bilateral, is a frequent symptom and often manifests in early childhood initially as sound conduction impairment. Later, sensorineural hearing loss and vestibular nerve dysfunction often develop.[63, 64, 67, 98]

Craniometaphyseal Dysplasia and Craniodiaphyseal Dysplasia

The *craniotubular dysplasias* have been divided into *Pyle's disease* (*metaphyseal dysplasia*), autosomal dominant and recessive craniometaphyseal dysplasia, craniodiaphyseal dysplasia, frontometaphyseal dysplasia (Fig. 24-32), Schwarz-Lèlek syndrome, dysosteosclerosis, and oculo-dento-osseous dysplasia.[78, 111] Craniometaphyseal dysplasia is characterized by metaphyseal widening of the tubular bones and bony overgrowth of the facial and skull bones (leontiasis ossea), which results in facial deformity from the early sclerosis of the skull and facial bones[112] (Fig. 24-33). Craniodiaphyseal dysplasia is characterized by massive craniofacial hyperostosis and sclerosis associated with the tubular bones. In both dysplasias, the cranial nerves may be affected due to stenosis and narrowing of the foramina.[78, 112] The genetic basis of both craniometaphyseal and craniodiaphyseal dysplasias has not yet been identified. Craniometaphyseal dysplasia is more often inherited as an autosomal dominant trait rather than by recessive transmission, while craniodiaphyseal dysplasia is likely to be transmitted as an autosomal recessive trait.[111–113]

Oculo-Dento-Osseous Dysplasia (Oculodentodigital Syndrome)

Oculo-dento-osseous dysplasia is presumed to be transmitted as an autosomal dominant trait; however, other patterns of inheritance are possible. Osteosclerosis of the skull, especially in the basal area, and enlargement of the mandible can be noted, although the coronoid process may be hypoplastic. Calcification in the basal ganglia and eyes may be present.[78] Enamel dysplasia, hypocalcification of the dentin, and other dental abnormalities are also present.

Dysosteosclerosis

Dysosteosclerosis has autosomal recessive inheritance. In early childhood, small stature, dental anomalies, and increased bone fragility can be noted. Thickening and sclerotic

Copyright © 2003, Mosby, Inc. All rights reserved.

changes in the cranial vault, skull base, and tubular bones may resemble osteopetrosis. However, this disorder can be differentiated by the presence of platyspondyly and lucency about expanded diametaphyseal segments of long bones.[78]

Pyle's Disease (Metaphyseal Dysplasia)

Pyle's disease (metaphyseal dysplasia) is a rare disorder with autosomal recessive or dominant inheritance. Marked expansion of the metaphyseal segments of tubular bones is noted, especially in the lower extremities. Changes in the skull are relatively subtle, and mild sclerosis of the cranial vault and skull base may be noted.[78]

Hereditary Hyperphosphatasia (Juvenile Paget's Disease)

Hereditary hyperphosphatasia (juvenile Paget's disease) is a rare autosomal recessive disease seen in infancy and childhood. It is characterized by generalized cortical thickening and by sustained elevation of serum alkaline phosphatase and urinary hydroxyprolamine. Thickening and

deossification of the skull base with bowing of tubular bones are observed.[67, 68, 78]

Pyknodysostosis

Pyknodysostosis is an autosomal recessive disease first evident in infancy and early childhood and characterized by short stature, small face and jaw, short hands and feet, hypoplasia of the nails, and a large cranium with frontal and occipital bossing.[66] Thickening of the base of the skull with sclerosis is often seen. The osteosclerotic change in patients with pyknodysostosis is uniform, and the long bones retain their normal external shape. Frequent fractures can be seen.[80]

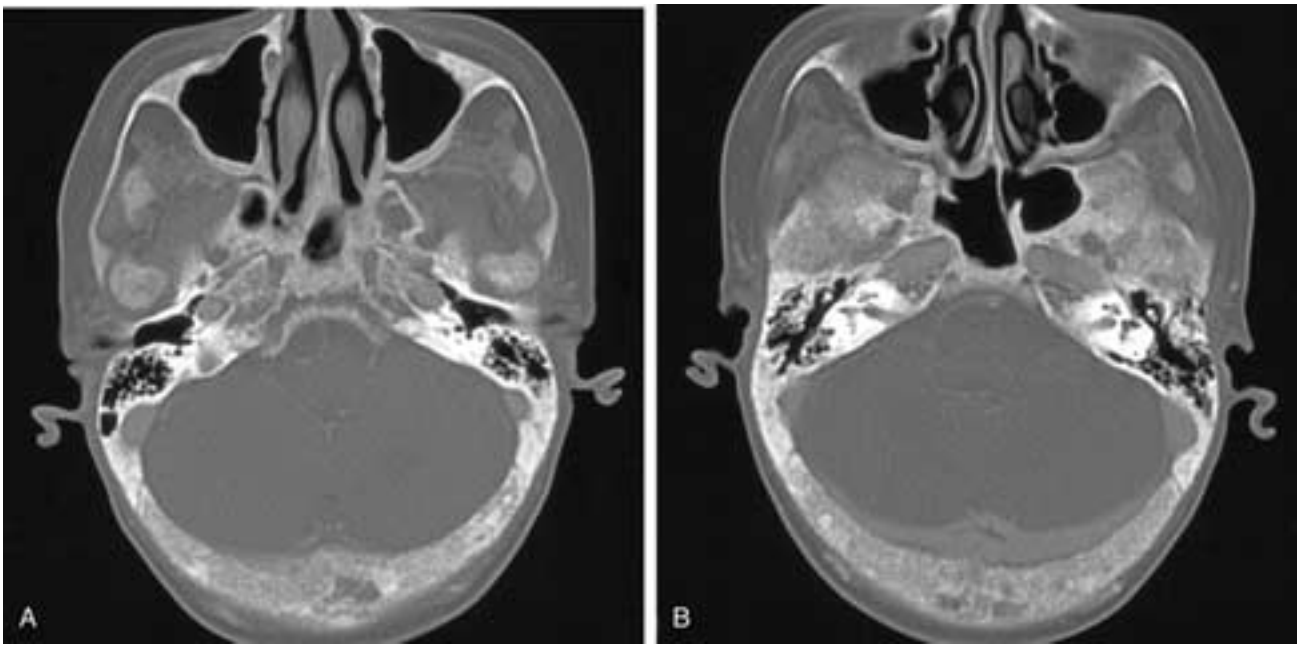
The middle ear is significantly narrowed, with impingement on the malleus and incus. The findings were symmetric. (Courtesy of Dr. Noriko Aida, Yokohama, Japan.)

Osteopathia Striata (Voorhoeve Syndrome)

Osteopathia striata (Voorhoeve syndrome) is a rare disorder with autosomal dominant inheritance with complete penetrance and variable expressivity.[114] The syndrome may result in generalized temporal bone sclerosis. Conductive hearing loss, especially at low frequencies, or mixed deafness can be present. Bony atresia or stenosis of the external auditory canals, middle ear cavities, and internal auditory canals, as well as abnormal ossicular chain fixation, may be observed.[99]

Hyperparathyroidism

Hyperparathyroidism may cause diffusely sclerotic bone changes, particularly with the secondary hyperparathyroidism, renal osteodystrophy. A progressive form of osteitis fibrosa cystica, osteofibrosis associated with localized cysts, rarefied and thinned cortex, distorted and blurred cancellous trabeculae, and deformity can be observed[61, 62] (Fig. 24-34). The manifestations of hyperparathyroidism are seen throughout the skeleton and are accompanied by other clinical and or laboratory manifestations.



VIEW IMAGE

FIGURE 24-34 Hyperparathyroidism. **A** and **B**, Axial CT images show diffuse sclerotic change in the skull base. The cancellous trabeculae of the involved bones are blurred. Changes are also noted in the mandibular condyle and coronoid processes on each side.

CLINICAL OVERVIEW

A discussion of tumors of the temporal bone is not complete without a discussion of tumors that involve the cerebellopontine angle (CPA). Because the fifth through twelfth cranial nerves exit the posterior cranial fossa either through the temporal bone or immediately adjacent to it, the clinical presentation of tumors of the temporal bone and the CPA is often similar. The temporal bone and the CPA also form the junctional region where neurosurgery and otologic surgery (neurootology) overlap.[1, 2] The most common clinical problems that warrant an imaging evaluation for a possible tumor include the investigation of the following: (1) sensorineural hearing loss, tinnitus, disequilibrium, or other symptoms of the CPA syndrome in search of an acoustic schwannoma (vestibular schwannoma) or one of the other tumors of this region; (2) pulsatile tinnitus or the jugular foramen syndrome in search of a paraganglioma or one of the other tumors or vascular lesions of the region; (3) peripheral facial nerve dysfunction in search of a tumor; and (4) a previously clinically identified tumor of the external canal. Each of these clinical settings has a different differential diagnosis, and the following discussion is organized with these settings in mind.

IMAGING OVERVIEW

Historically the investigation of acoustic schwannomas (neuromas, vestibular schwannomas) and other tumors of the CPA and the temporal bone has progressed through the use of plain films, tomography, pneumoencephalography, positive contrast meatocisternography, and angiography.[2–7] With each of these modalities, diagnosis was based on indirect signs of a mass such as erosion or displacement of either vessels or contrast material. Modern imaging uses predominantly either magnetic resonance (MR) imaging or computed tomography (CT). Both of these modalities image the lesion directly. These modalities have been indispensable allies to the recent advances in surgical management of temporal bone tumors, and the discussions of imaging in this section are directed almost completely to them.[8]

Before clinical availability of paramagnetic contrast agents, Gentry, Jacoby, Turski, and others, comparing the diagnosis of 75 CPA and petromastoid masses by MR imaging and CT, found that both modalities were accurate and had similar capabilities for detecting lesions of neoplastic, nonneoplastic, or vascular origin.[9] However, since the introduction of paramagnetic contrast agents, the capability of MR imaging has greatly improved. At present, when a retrocochlear lesion is the suspected cause of vestibulocochlear symptoms, gadolinium-enhanced MR (Gd-MR) imaging is considered to be the most reliable study.[10] When a labyrinthine or cochlear lesion is suspected, high-resolution CT with bone detail is usually the initial study.[11] MR imaging is preferred over CT for the investigation of cranial nerve dysfunctions, and in most cases, if the MR imaging examination is normal, no other imaging studies are performed. A comprehensive examination typically includes thin-section (1–3 mm) T1-weighted (short TE, short TR) images through the posterior cranial fossa, before gadolinium, fat-suppressed corresponding T1-weighted images after gadolinium, and thicker (5–6 mm) T2-weighted (long TE, long TR) and/or FLAIR (fluid attenuated inversion recovery) images surveying the brain. Supplementary sequences, such as diffusion-weighted images, gradient echo sequence, and MR angiography may be added.[12–15] Recently developed constructive interference steady state (CISS) and fast spin echo techniques use heavily T2-weighted images without gadolinium.[16, 17] Both of these sequences have succeeded in consistently outlining the facial nerve, the cochlear and both vestibular divisions of the acoustic nerve, the anterior inferior cerebellar artery (AICA), and the tumors in the CPA and internal auditory canal (IAC).

On the other hand, CT is still preferred over MR imaging as the initial imaging modality to investigate pulsatile tinnitus, conductive hearing loss, or a retrotympanic mass that suggests the presence of a paraganglioma or a vascular anomaly. If a mass is found localized within the tympanic cavity or if a vascular anomaly is recognized, no other imaging is usually needed. MR imaging and CT, however, must not be considered mutually exclusive, and when diagnostically indicated, each may be employed to supplement the other. In fact, both MR imaging and CT are usually required for full assessment of skull base lesions.[18] Today, angiography is reserved for the detection of arterial stenotic lesions and arteriovenous fistulae, for the evaluation of tumor vascularity, and for preoperative embolization.

ACOUSTIC SCHWANNOMAS (NEUROMAS)

Incidence and Terms

Acoustic schwannomas account for about 8% to 10% of all intracranial tumors and about 60% to 90% of all CPA tumors (Table 25-1).[19–21] They are slightly more common in women than in men. Most of the tumors appear in patients between 30 and 70 years of age, with the majority of lesions occurring in those between 40 and 60 years of age.[22] Occasionally these tumors appear in young adults or children without any of the stigmata of neurofibromatosis.[23, 24] Although more than 25 names, including those commonly used

such as neurinoma, neurilemmoma, and neuroma, have been applied to the acoustic nerve tumor, most authorities regard schwannoma as the most appropriate term.[19, 25–28] As most of these lesions arise from the vestibular nerve, the term *vestibular schwannoma* is often used as the most accurate term.

Pathology

A schwannoma is a benign, slowly growing, encapsulated neoplasm that originates in the nerve sheath and is composed of Schwann cells in a collagenous matrix.[26, 27] By comparison, a neurofibroma is a benign, relatively circumscribed, nonencapsulated neoplasm that consists of proliferating axons and Schwann cells. The absence of a capsule, Verocay bodies, hyaline thickening of vascular walls, and Antoni A and B growth patterns (see the following discussion) are features that distinguish a neurofibroma from a schwannoma. However, in some cases these two benign nerve sheath tumors cannot be differentiated pathologically.

For unexplained reasons, schwannomas arise from the acoustic nerve (CN VIII) much more often than from any other cranial nerve, and the vestibular division is far more commonly involved than the cochlear division.[25, 29, 30] Hence the Consensus Development Panel recommended that acoustic schwannomas be termed *vestibular schwannomas*.[31] Because the glial–Schwann cell junction of the acoustic nerve lies (with some variation) near the internal acoustic porus, and because schwannomas may arise from any portion of the nerve between this zone of transition and the fundus of the IAC, these tumors arise within the IAC, at the porus, or occasionally in the CPA cistern.[19, 32] A schwannoma is typically composed of Antoni type A and type B tissue. Type A tissue is compact, with elongated spindle cells in irregular streams, often having a tendency to form palisades. Type B tissue, often intermingled with type A, is characterized by a loose texture, often with cyst formation. Microcystic and, less commonly, macrocystic changes and hemorrhage characteristically develop in type B tissue.[19, 25] Most acoustic schwannomas consist predominantly of type A tissue. With increasing size of the lesion, there is a tendency for tumor cellularity to decrease and degenerative changes and vascularity to increase.[22] Kasantikul, Netsky, Glasscock, and others have also noted that a hemangiomatous component is often present.[22] Most tumors grow at a slow (0.02 cm per year) or medium rate (0.2 cm per year), but a small percentage grows as much as 1 cm or more per year.[33] Larger tumors are found in younger patients, in females, and in patients with no intracanalicular component.[34] Acoustic schwannomas are more common in women and tend to be larger and more vascular. Pregnancy has been noted to accelerate symptoms and tumor growth.[35] On the other hand, intracanalicular tumors may be more common in men.[36]

Malignant schwannomas are extremely rare and usually are seen in patients with neurofibromatosis 1.[25, 37, 38] An astrocytoma arising in the glial portion of the acoustic nerve also has been reported.[39]

Bilateral Acoustic Schwannomas

The neurofibromatoses consist of at least two distinct disorders, the genes for which are located on separate chromosomes.[40–42] Von Recklinghausen's neurofibromatosis, which manifests primarily peripherally and is now called neurofibromatosis 1 (NF1), affects approximately 100,000 people in the United States. Bilateral acoustic neurofibromatosis, which manifests primarily centrally and is now called neurofibromatosis 2 (NF2), affects several thousand Americans. Both of these disorders may be inherited as an

Copyright © 2003, Mosby, Inc. All rights reserved.

autosomal dominant trait or acquired by spontaneous mutation.

Patients with NF1 have multiple brown skin macules (café au lait spots), intertriginous freckling, iris hamartomas (Lisch nodules), multiple neurofibromas (especially plexiform neurofibromas), optic gliomas, and distinctive osseous lesions.[37, 38] They may have Schwann cell tumors on any nerve, but an estimated 5% or fewer have acoustic tumors.[38, 43, 44]

Patients with NF2 (Fig. 25-1) have bilateral acoustic schwannomas (96%) commonly accompanied by other Schwann cell tumors and multiple meningiomas, neurofibromas, and glial tumors.[37, 45] They are not associated with optic gliomas or malignant tumor degeneration, which occur in NF1.[44, 46] Members of some kindreds also develop ependymomas, usually in the cervical cord.[47] In NF2 patients with concurrent meningiomas, the growth of the schwannomas accelerates 10-fold, with infiltration from the adjacent meningiomas.[48] A rare case of schwannoma and meningioma coexisting within the same tumor has also been reported in an NF2 patient.[49]

Compared with unilateral schwannomas, bilateral acoustic schwannomas tend to develop early, with many appearing before the patient is 21 years of age; about half of these individuals are symptomatic by the age of 25 years.[40] These schwannomas are more liable to infiltrate the facial and cochlear nerves than are unilateral types and present a formidable challenge to surgical management.[50] Early detection and resection appear to offer the best hope of hearing preservation.[40, 44, 46, 51, 52] MR imaging screening at an early age (10 to 12 years) in all children with an appropriate family history has been recommended regardless of the auditory-brainstem response.[37, 52] Careful evaluation of the contralateral ear of young patients (under 30 years of age) with unilateral acoustic schwannoma is advised, as is routine imaging of the cervical spine.[37] First-generation relatives of patients with either bilateral acoustic schwannomas or unilateral tumors of early onset also should be counseled and, if found appropriate, screened with imaging.[50, 53] Prenatal diagnosis, however, is not yet feasible.[33]

With regard to treatment, direct placement of acoustic brainstem implants (ABI) adjacent to the cochlear nuclei in patients deafened by bilateral tumor removal is now FDA approved for clinical use. The majority of recipients report daily use of their devices and satisfaction with the decision to receive the ABI.[54–58]

Clinical Evaluation

The most common symptoms associated with acoustic schwannomas are those caused by pressure on the cochlear and vestibular divisions of the acoustic nerve, namely, sensorineural hearing loss, tinnitus, and disequilibrium.[59, 60] Frequently, patients with acoustic schwannoma have difficulty understanding speech in the affected ear. This condition is referred to as decreased speech discrimination.

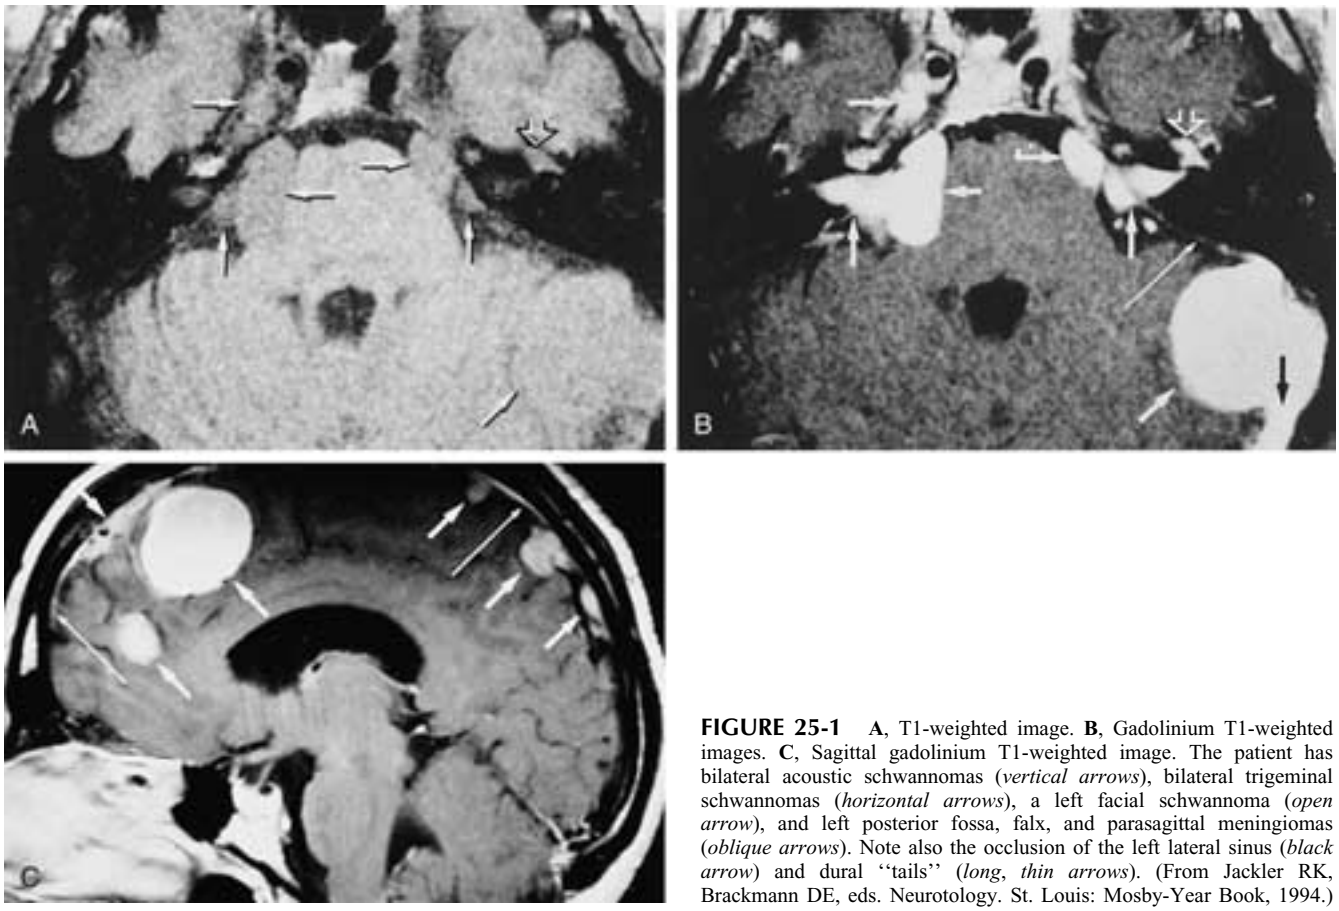

FIGURE 25-1 **A**, T1-weighted image. **B**, Gadolinium T1-weighted images. **C**, Sagittal gadolinium T1-weighted image. The patient has bilateral acoustic schwannomas (*vertical arrows*), bilateral trigeminal schwannomas (*horizontal arrows*), a left facial schwannoma (*open arrow*), and left posterior fossa, falx, and parasagittal meningiomas (*oblique arrows*). Note also the occlusion of the left lateral sinus (*black arrow*) and dural ''tails'' (*long, thin arrows*). (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)

The problem may not be evident to the patient during conversation because of the normal hearing in the contralateral ear. However, when using the abnormal ear, the patient may complain of difficulty in understanding speech on the telephone. The symptoms are usually slowly progressive, evolving over months or years; in one series, the median duration was about 2 years.[22] The duration of symptoms is not necessarily correlated with tumor size. Some authors have noted an inverse correlation, with up to 10% of patients with acoustic schwannomas having only tinnitus as a presenting symptom.[22]

Facial nerve manifestations such as twitching or weakness are relatively uncommon.[60, 61] Instead, larger tumors are more likely to cause trigeminal manifestations such as facial numbness and loss of the corneal reflex.[59, 60] Still larger tumors may cause deficits of the lower cranial nerves, cerebellar signs and symptoms, or signs and symptoms of hydrocephalus.[60, 61] Rarely, an acoustic schwannoma, usually a large one, can present as a subarachnoid hemorrhage.[62–65]

Among the commonly employed clinical laboratory tests, brainstem electric response audiometry (BERA) is considered the most sensitive preimaging test for acoustic schwannoma.[54] The ability to understand speech is measured as a ''speech discrimination'' score, and a low score suggests an acoustic schwannoma. Until MR imaging became widely available, the diagnostic steps typically included a history and physical examination, an audiogram, a brainstem-evoked response, CT with contrast, and then, if necessary, a gas-CT cisternogram.[66, 67] MR imaging is now clearly the imaging method of choice.[10, 68] Some groups even advise Gd-MR imaging for all patients with unilateral sensorineural hearing loss or unexplained tinnitus, without performing BERA.[60, 69] Schmidt and colleagues have concluded that BERA cannot be relied on for detection of small acoustic neuromas and should not be used to determine whether MR imaging should be performed when an acoustic neuroma is suspected clinically.[70] Newly developed noncontrast, thin-section, T2-weighted imaging sequences may become a screening modality (Fig. 25-2).[71] These techniques are less expensive than comprehensive studies for screening; however, the true goal of imaging remains exclusion of acoustic tumor. The contrast-enhanced, T1-weighted sequence remains the easiest examination to do and interpret, with the highest negative predictive value in exclusion of vestibular schwannoma as a cause of sensorineural hearing loss.[72] Contrast-enhanced examinations are also of value in demonstrating inflammatory conditions of the nerve, which would be enhanced by the gadolinium but show little swelling.[73]

Treatment

Whenever feasible, the accepted treatment for acoustic schwannoma is surgical resection.[31] With microsurgery, total tumor removal and functional preservation of the facial nerve, with low morbidity and mortality, is now the rule.[74, 75] In the 1990s, attention focused on hearing preservation, and it is generally agreed that hearing preservation is more successful with removal of small tumors.[52, 76] Early detection therefore continues to be emphasized, and high-quality MR imaging contributes immeasurably to these goals. New MR techniques provide the surgeon with more useful information when an intracanalicular tumor is detected.[14] It is often possible to determine if the tumor is located in the facial nerve or in one of the three branches of the vestibulocochlear nerve.[77] Sartoretti-Schefer and colleagues have identified the entire course of the facial nerve and nerve tumor relationships in small vestibular schwannomas utilizing 3D T2-weighted sequences.[78] While this preoperative information may not change the surgical approach in vestibular schwannomas, it can influence the surgical technique and approach in other CPA masses.[79] MR imaging can also be used to predict hearing preservation, which is found to be four times more likely when the labyrinthine signal is normal on 3D-CISS images.[80] Other investigators found that the absence of cochlear contrast enhancement ipsilateral to tumor correlates well with preservation of hearing following surgery.[81]

For the treatment of acoustic tumors, there are basically three surgical approaches—translabyrinthine, suboccipital, and middle (cranial) fossa—and a number of variations and combinations thereof.[2, 82–85] There is considerable variation in the surgical approach used, but in general, small tumors with preservation of hearing are operated on using the middle fossa or the suboccipital approach.[85, 86] In general, the middle fossa is favored for small tumors involving the lateral IAC, and the suboccipital retrosigmoid approach is preferred for small tumors in the CPA and the medial IAC. The translabyrinthine approach is used for patients with poor hearing or large tumors. However, some surgeons prefer the translabyrinthine approach for tumors of all sizes, and others prefer the suboccipital approach in most cases.

No consensus exists for grading the size of acoustic tumors. However, one might consider tumors that are either intracanalicular or those that extend up to 0.5 cm into the CPA as small tumors; lesions with 0.5 to 2 cm cisternal components as medium-sized tumors; lesions with 2 to 4 cm cisternal components as large tumors; and lesions with greater than 4 cm cisternal components as giant tumors.[22, 84, 87, 88]

Acoustic tumors in elderly or high-risk patients are followed by annual CT or MR imaging until their growth rates can be determined.[89, 90] Vestibular schwannomas can be managed safely in the elderly patient by serial MR

Copyright © 2003, Mosby, Inc. All rights reserved.

scanning. When significant tumor growth or neurologic deterioration is demonstrated, early surgical intervention may be required to avoid complications.[53, 91–98] In one series of 41 patients over 65 years of age, who were followed for an average of 3.5 years, 21 patients demonstrated tumor growth at an average rate of 0.322 cm per year.[99] Only five patients required intervention. No patients developed significant complications. No correlation could be found between initial tumor size and subsequent tumor growth. In a series of 116 patients over 65 years of age who had acoustic tumor surgery, with all but 10 having total tumor removal, the operative mortality rate was less than 1%.[100] Alternatively, acoustic tumors, especially in high-risk patients and those with bilateral tumors, may be treated by stereotactic radiosurgery using sharply collimated and focused cobalt-60 sources (gamma knife).[101] In a study of 86 patients with vestibular schwannomas, low-dose gamma knife radiotherapy was found to be effective for both small and large tumors up to 4 cm in size.[102] The tumor control rate was 81%. An increase in tumor size up to 2 years after radiotherapy is likely to be followed by regression. Dynamic changes in the enhancement pattern and T2 abnormalities of the adjacent brain are expected in serial MR imaging following radiotherapy.[102] Although the surgical results are excellent in preserving hearing in patients with small intracanalicular schwannomas, radiotherapy has results comparable to those of surgery in patients with small and mid-sized tumors.[102, 103] Patients with medical contraindications to surgery and residual tumors are good candidates for radiotherapy.

CT and MR Imaging Appearance

Size, Location, and Configuration

Acoustic schwannomas range in size from a few millimeters to 5 to 6 cm (Figs. 25-2 to 25-8), and tumors as large as 8 cm have been encountered.[104] A small percentage of acoustic schwannomas are entirely intracanalicular, in which case they are usually cylindrical in shape, are less than 1 cm in length, fill the IAC, and have a convex medial margin (Figs. 25-2 to 25-4).[105] The majority of medium-sized schwannomas have a spherical cisternal component up to 2 cm in diameter centered at the acoustic porus and a stem of tumor that extends into the IAC and expands the porus to a funnel shape. The overall appearance of the tumor resembles an ice-cream cone or a mushroom (Fig. 25-4). Tumors between 2 and 4 cm may be considered large, and usually are ovoid or slightly lobulated. Their petrous surface remains centered on the acoustic porus, and their long axis lies parallel to the petrous surface (Fig. 25-5). The very large or ''giant'' tumors often arise from the cisternal portion of the nerve and possess little or no canalicular component. The majority (85%) of schwannomas show acute angles at the bone–tumor interface (Figs. 25-4, 25-5, 25-7 and 25-8), in contrast to meningiomas, which tend to show obtuse angles (75%) (Fig. 25-9).[106] Acoustic schwannomas seldom if ever herniate through the tentorium.[32]

CT Density

On noncontrast-enhanced CT, the majority (64%) of acoustic schwannomas are isodense with the adjacent

New York: Marcel Dekker, 1987;296.)

cerebellum and are not discernible without IV contrast.[20] The remaining tumors are either slightly hypodense, hyperdense, or of mixed density. Calcification or detectable hemorrhage is rare in untreated tumors.[64, 104]

CT contrast enhancement occurs in nearly 90% of untreated tumors, and the enhancement is usually homogeneous and dense.[104] Most acoustic schwannomas rapidly enhance. The enhancement declines rapidly within 15 minutes after completion of contrast infusion, then less rapidly within the next 45 minutes, and residual enhancement may remain for hours.[107] Some investigators, however, indicate that maximum enhancement occurs about one half hour after infusion, and some researchers recommend a slight delay between infusion and scanning because the tumor enhancement may not be as obvious during the ''vascular'' phase.[108] The contrast must be given time to move from the intravascular compartment to the extravascular tissue.

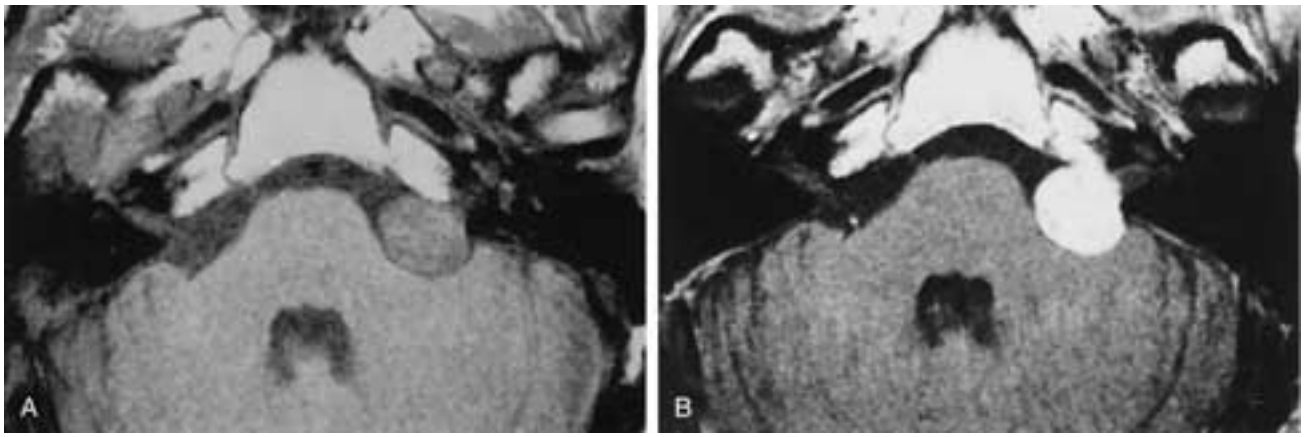
Some tumors show irregular central lucencies or inhomogeneous enhancement. The initially unenhanced portions of the schwannoma may take many minutes to attain full enhancement, and tumors with such an appearance contain prominent cystic components at surgery. Loss of contrast enhancement is common after stereotactic radiotherapy.[101]

Rarely, an arachnoid cyst may develop around a tumor and become the dominant lesion.[109]

MR Imaging Intensity

On MR imaging, as on CT, small and medium-sized acoustic schwannomas are most likely to be homogeneous, and large tumors are most likely to contain internal zones of inhomogeneity (Figs. 25-6 to 25-8).[20] Cysts may be intra- or extramural and single or multiple.[110]

On T1-weighted images, schwannomas are usually isointense or mildly hypointense relative to the pons and are hyperintense to CSF. On T2-weighted images they are mildly hyperintense to the pons and iso- to hypointense to CSF (Fig. 25-4).[68, 111, 112] With very long TR and TE, the CSF gives a very high signal, and almost all acoustic schwannomas, particularly those limited to the IAC, have a lower signal than the CSF when these imaging parameters are used. Thus the CSF becomes a natural contrast for detecting the tumor. Previously, such sequences took too long to perform, and patient motion limited their usefulness. Recently, fast spin-echo technology has allowed such imaging in a reasonable time interval (see Fig. 25-2).



VIEW IMAGE

Tumors large enough to deform the pons are readily recognizable on both T1-weighted and T2-weighted images. Tumors too small to deform the pons stand out well against the hypointense CSF on T1-weighted images (Fig. 25-3), but they may be obscured by the nearly isointense CSF on T2-weighted images.[68, 112, 113]

Displaced tributaries of petrosal and capsular veins, which are difficult if not impossible to see on CT, are often recognizable on MR imaging in medium-sized and large tumors (Fig. 25-7).[68] Intratumoral hemorrhage, at various stages of hemoglobin breakdown, may also be detected on MR imaging.[114]

Acoustic schwannomas enhance intensely after intravenous administration of a gadolinium contrast agent on T1-weighted images (Figs. 25-1, 25-3 to 25-8).[115] The sensitivity of contrast-enhanced, T1-weighted MR imaging can approach 100% in detecting schwannomas.[73] With a small field of view, the voxel size can be decreased to 0.7 × 0.4 × 0.3 mm.[116] In a recent series, both contrast T1-weighted and high-resolution T2-weighted images detected tumors ranging from 0.06 to 3.0 cm^3.[117]

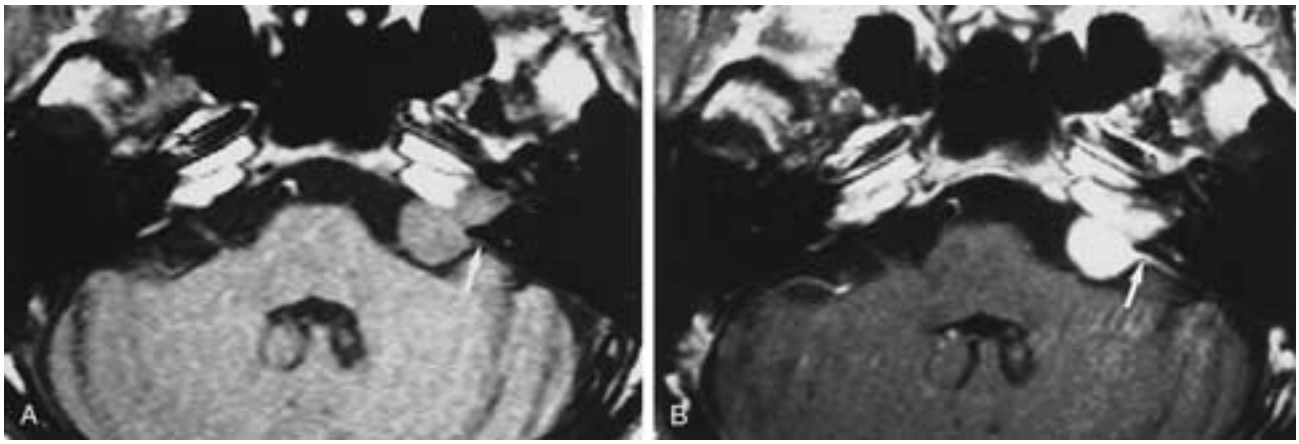
As a group, acoustic schwannomas enhance substantially more than meningiomas, neurofibromas, and paragangliomas on T1-weighted, contrast-enhanced spin-echo images.[118] However, enhancement varies greatly in tumors of the same type and overlaps among different tumor types. Unless enhancement is marked, it is of limited value in differentiating schwannomas from other extraaxial tumors.[118] In contrast to meningiomas, schwannomas rarely show dural ''tails'' (Fig. 25-10).[119]

Secondary Changes

Because acoustic schwannomas are extraaxial, as they grow they enlarge toward the cerebellopontine junction and displace the brainstem to the contralateral side. Indirect signs of an extraaxial mass (such as widening of the ipsilateral CPA and the quadrigeminal cisterns, narrowing of the contralateral cisterns, and displacement and compression of the fourth ventricle) accompany the larger tumors (Figs. 25-5 to 25-7). Acoustic schwannomas, however, do not extend anterosuperiorly above the dorsum and, unlike meningiomas, extremely rarely herniate into the middle fossa.[32] The incidence of hydrocephalus correlates roughly with tumor size, and one report noted hydrocephalus in 17 of 44 patients in whom a tumor measuring 3 cm or more was present.[120] Edema of the adjacent brain also may be associated with large acoustic schwannomas.[20, 121]

Bone changes associated with acoustic schwannomas are limited to the IAC (Figs. 25-1, 25-4 to 25-7 and 25-10). By comparing the normal IAC to the abnormal side and using the criteria of a difference in canal height of more than 2 mm, a shortening of the posterior wall of the canal of more than 3 mm, a downward displacement of the crista falciformis, and the presence of focal erosion, Valvassori found abnormal IACs on polytomography in 78% of surgically verified tumors.[6] On high-resolution CT the incidence of bone changes is probably comparable or higher. Tumors arising from the intracanalicular portion of the nerve typically cause flaring of the porus acousticus as they enlarge (Figs. 25-1, 25-4 to 25-7 and 25-10), whereas those arising from the cisternal portion may cause little or no erosion (Fig. 25-8). Regarding canal size, bilateral enlargement of the IAC in the absence of intracanalicular tumors may be seen in neurofibromatosis, and unilateral asymmetry also may be seen on rare occasions.[1, 109, 122, 123]

In a series of 86 patients treated with stereotactic radiotherapy, three patterns of enhancement were seen: (1) transient loss of contrast enhancement (84%), (2) continuous increase in contrast enhancement (5%), and (3) no change in contrast enhancement (11%). There was no significant correlation between changes in tumor volume and tumor enhancement.[102] The same investigators found T2 abnormalities in the adjacent brain parenchyma in 19 patients (31%). These changes disappeared or improved in 14 patients. There was no correlation between dose, tumor size, and the T2 signal changes. A series of 89 tumors treated with stereotactic radiotherapy showed that, on evaluation approximately 12 months after treatment, most vestibular schwannomas remained stable (73%), some shrank (22%), and a few grew (3%).[101] By contrast, most untreated tumors remained stable (59%), many grew (38%), and a few shrank (3%) (Fig. 25-11).[101] About 5 to 15 months after radiation



VIEW IMAGE

therapy, the tumors frequently lost central enhancement (79%), which in some cases returned with time. In the adjacent pons and cerebellar peduncle, contrast enhancement on T1-weighted images may develop. Hyperintensity on T2-weighted images, which did not closely correspond to neurologic symptoms, appeared in 9% of patients. Delayed trigeminal nerve enhancement and development of hydrocephalus were also observed in some patients.[101, 124] Some tumors may continue to grow and require resection.[97, 121]

DIFFERENTIAL DIAGNOSIS OF TUMORS OF THE INTERNAL AUDITORY CANAL AND THE CEREBELLOPONTINE ANGLE

Statistics and Categorization

Although by far the most common tumor associated with the CPA syndrome is the acoustic schwannoma, many other neoplastic and nonneoplastic mass lesions occur in the region (Table 25-1).

Brackmann and Bartels, reviewing 1354 CPA tumors, excluding paragangliomas, found 91.3% acoustic schwannomas, 3.1% meningiomas, 2.4% primary cholesteatomas (epidermoid cysts), 1.2% facial nerve schwannomas, and 0.2% schwannomas of other posterior fossa cranial nerves. There were 25 rare tumors, including 7 arachnoid cysts, 4 hemangiomas, 1 hemangioblastoma, 2 astrocytomas, 2 medulloblastomas, 3 metastatic tumors, 2 dermoids, 2 lipomas, 1 malignant teratoma, and 1 chondrosarcoma.[21]

Similarly, Valavanis et al., analyzing 455 CPA lesions, found the following among the primary tumors: 60.5% acoustic schwannomas; 6.8% meningiomas; 3.7% epidermoid cysts; 2% arachnoid cysts; 4% schwannomas of the fifth, seventh, ninth, tenth, and eleventh cranial nerves; 0.2% primary melanomas; and 0.7% hemangiomas. Among secondary tumors of the CPA, the following were found: 10.3% paragangliomas (chemodectomas), 0.2% germinomas, 0.4% chondromas, 1.8% chordomas, and 1.3% cerebellar and bone tumors; among vascular lesions: 0.9% aneurysms, 0.9% arteriovenous malformations, and 3.7% megadolichobasilar anomalies. There were also 2.6% metastases.[20]

Both of the above series are in substantial agreement with the often-cited series of 205 CPA tumors of Gonzalez Revilla, which consisted of 75.1% acoustic schwannomas, 6.3% meningiomas, 6.3% epidermoids, 4.9% nonacoustic schwannomas, 0.5% primary melanomas, 0.5% paragangliomas, and 6.4% cerebellar and petrous bone tumors infiltrating the CPA.[125]

Thus the four most common tumors are the same in all three series: acoustic schwannoma, meningioma, epidermoid cyst, and nonacoustic posterior fossa schwannoma. Together they account for 75% to 98% of all CPA mass lesions.

Although the probability of a CPA mass being an acoustic schwannoma is 60% to 90%, the remaining possibilities are diverse and numerous. In practice, the imaging differential diagnosis of a CPA lesion may be simplified by classifying the possible lesions into groups by their imaging appearance (Table 25-2). Essentially there are

Table 25-2
CT/MR IMAGING DIFFERENTIAL DIAGNOSIS CATEGORIES OF CPA LESIONS

	Location	Incidence	Type
I	Extraaxial	Most common	Acoustic schwannoma
II	Extraaxial	Common	Meningioma
III	Extraaxial	Common	Epidermoid (and other cysts: arachnoid cysticeral, lipoma)
IV	Extraaxial	Rare	Nonacoustic posterior fossa schwannomas (V, VII, IX, X, XI, XII)
V	Extraaxial	Rare	Vascular lesions (VBD,* aneurysm, AVM,† hemangioma, AICA‡ loop, siderosis)
VI	Extraaxial	Common	Paraganglioma
VII	Extraaxial	Rare	Bone lesion (benign or malignant: primary or metastatic)
VIII	Intraaxial	Rare	Astrocytoma, ependymona, papilloma, hemangioblastoma, metastasis, etc.

**VBD,* Vertebrobasilar dolichoesctasia.
†*AVM,* Arteriovenous malformation.
‡*AICA,* Anterior inferior cerebellar artery.

three common extraaxial tumors (acoustic schwannoma, meningioma, and epidermoid cyst) (Table 25-3), two groups of rare extraaxial lesions (nonacoustic posterior fossa schwannomas and vascular masses), two groups of extradural masses (paragangliomas and bone lesions), and finally, the intraaxial lesions. For simplicity, rare nonenhancing masses such as lipomas, dermoids, and arachnoid and cysticercal cysts may be placed in the same group as epidermoid cysts.

The three most common lesions in adults—acoustic schwannoma, meningioma, and epidermoid cyst—are the same in older teenagers. However, in younger children, acoustic schwannomas are extremely rare, and gliomas, which are capable of enlarging the internal acoustic canal, are the most common cause of CPA tumors.[126]

Meningiomas and Simulants

Meningioma arises from the meningothelial arachnoid cell and accounts for 13% to 18% of all primary intracranial tumors.[27] In the CPA, it is a distant second to acoustic schwannoma in incidence, and it is the lesion offering the most difficulty in the differential diagnosis of acoustic schwannoma (Figs. 25-13 to 25-16).[20, 21, 106] Like acoustic schwannomas, meningiomas are extraaxial. However, unlike acoustic schwannomas, they are usually eccentric to the porus.[127] Also unlike acoustic schwannomas, which seldom if ever herniate into the middle fossa, meningiomas frequently do (56%).[106, 127, 128] Meningiomas also may extend into the middle fossa by growth through the tentorium (19%) or temporal bone (Fig. 25-15).[106, 128] In size they are usually moderate to large compared with acoustic schwannomas.[9]

Meningiomas are almost always broad-based against a dural surface such as the posterior petrous wall. Their configurations generally fall into three groups. Unlike acoustic schwannomas, which are by and large spherical or ovoid, most meningiomas are hemispherical (Figs. 25-12 to 25-15).[127] Consequently, most meningiomas (75%) show obtuse bone tumor angles, while schwannomas tend to show acute angles (85%) (Fig. 25-9).[106] Some meningiomas are plaquelike (en plaque) and often deeply infiltrate the underlying bone (Fig. 25-16). A few meningiomas appear nearly rounded and by configuration are more difficult to distinguish from schwannomas.

Meningiomas are either isodense (31%) or, more often, hyperdense (69%) on noncontrast CT.[106] Unlike schwannomas, they are often calcified (25%), usually homogeneously and sometimes densely.[104, 106] More than 90% show homogeneous enhancement inversely proportional to their precontrast density.[106] CPA meningiomas are isointense or slightly hypointense to gray matter on T1-weighted images but are extremely variable in intensity on T2-weighted

Table 25-3
COMPARISON OF SALIENT CT AND MR IMAGING FEATURES OF THE THREE MOST COMMON CPA LESIONS

	Acoustic Schwannoma	Meningioma	Epidermoid Tumor
Location	Centered to IAC	Posterior petrous wall most eccentric to IAC	Anterolateral or posterolateral to brainstem
Bone changes	Most enlarging IAC	Occasional hyperostosis	Occasional erosion
Shape	Spherical or ovoid, occasionally lobulated, acute bone tumor angle	Hemispherical, rarely plaque-like, may herniate, obtuse bone tumor angle	Variable with tendency to dumbell into middle fossa or contralateral CPA
Density	Mostly isodense, a few slightly hypodense or hyperdense	Isodense or mostly slightly hyperdense, some calcified	Mostly about CSF density, rarely denser than brain, occasional peripheral calcification
CT enhancement	Moderate to marked, often with inhomogeneous enhancement	Marked and homogeneous	Nonenhancing
Intensity T_1W image	CSF < M ≤ Gr	CSF < M ≤ Gr	CSF ≤ M < Gr
Intensity T_2W image	≤CSF	Variable	≤CSF
MR enhanced	Marked, some ''cystic''	Moderate	Nonenhancing

FIGURE 25-12 Diagrammatic representation of the locations of 19 meningiomas producing CPA symptoms (left and right sides combined). (From House JW, O'Conner AF. Handbook of Neurotological Diagnosis. New York: Marcel Dekker, 1987;290.)

images, more so than any other CPA mass lesion (Figs. 25-14 to 25-16).[9] When the intensity of a CPA mass is equal to or less than that of gray matter on T2-weighted images, meningioma is the most likely diagnosis.[9] Otherwise, signal intensity as a diagnostic criterion for meningioma is far less helpful than location and configuration. The wide variation in signal intensity among meningiomas appears to reflect the diversity of histopathology in meningiomas. Tumors significantly hypointense to brain cortex tend to be composed primarily of fibrous or transitional elements. Tumors significantly hyperintense to brain cortex tend to be composed primarily of syncytial or angioblastic elements.[129, 130] Nevertheless, accurate prediction of the histology and behavior of meningioma by imaging is not possible.[131–133] The metabolic rate, as revealed by positron emission tomography (PET), may be a better prognosticator of tumor aggressiveness and recurrence.[134]

Other MR imaging findings in meningioma include marginal pial blood vessels manifesting as surface flow voids, surface CSF spaces or clefts, and arterial feeders to the tumor, which are seen as arborizing flow voids (Fig. 25-15).[9, 135, 136] These findings are less commonly seen in infratentorial than in supratentorial meningiomas.[9]

Heterogeneity in meningiomas may be caused by calcifications and cystic foci, and perifocal edema is occasionally discernible on both CT and MR imaging.[9, 104, 135] Marked peritumoral edema, absence of visible calcium aggregates, nonhomogeneous contrast enhancement with nonenhancing ''cystic'' components, and poorly defined irregular borders suggest aggressive or invasive characteristics more commonly found in the angioblastic and syncytial variants.[137]

Dural thickening surrounding a meningioma (''dural tail,'' ''meningeal sign,'' or ''flare sign'') is best seen on Gd-MR imaging and is found in 52% to 72% of the cases (Figs. 25-14 to 25-16).[138–140] In most cases, ''dural tails'' represent reactive rather than neoplastic changes.[139, 141–143] Much less frequently, peritumoral dural thickening also has been found in other tumors, including oligodendroglioma, schwannoma, glioblastoma, and metastases.[119, 140, 142] Dural thickening bordering a meningioma extending into the

The IAC extension and margins of the tumor are better delineated on CISS images than on T2-weighted images.

VIEW IMAGE

IAC may simulate the stem of an acoustic schwannoma.[138] Underlying hyperostosis is seen infrequently but is highly characteristic when present (Figs. 25-13C).[20, 106] The IAC is rarely enlarged. The treatment for meningioma is surgical, and local recurrences are not uncommon.[27, 144] In a series of 134 CPA meningiomas, complete tumor removal was accomplished in 95%.[145] Since complete surgical removal of skull base meningiomas has a high morbidity rate, radiotherapy should be considered as an adjunctive or alternative method of therapy.[146]

Several rare neoplastic and inflammatory processes involving the meninges may simulate meningiomas on CT or MR imaging and should be suspected when the presenting symptoms or imaging features of the lesions are not entirely typical of meningioma. Among the neoplasms are leptomeningeal metastasis (meningeal carcinomatosis) (Figs. 25-17 and 25-18), primary meningeal lymphoma, and primary malignant melanoma.[147–153] Among the inflammatory diseases are meningeal sarcoidosis, Lyme disease, tuberculosis, syphilis, and idiopathic hypertrophic cranial pachymeningitis (Fig. 25-19).[154–156] All of these processes may appear as diffuse dural thickening simulating en plaque meningiomas or localized dural-based masses simulating sessile meningiomas. However, they are not expected to elicit underlying hyperostosis, produce intratumoral calcification, or possess discernible feeding or draining meningeal vessels.

Epidermoid and Other Cysts

Also called primary cholesteatomas or pearly tumors, congenital intradural epidermoid cysts (or tumors) are the third most common tumor in the CPA (Figs. 25-20 to 25-22).[20, 21] Although congenital, they do not present clinically until young or middle adulthood. Originating from ectodermal cell rests, they consist of stratified squamous epithelial linings surrounding desquamated keratin.[27] As the contents slowly accumulate, the lesions often reach considerable size and yet cause only minimal symptoms.[157] The duration of symptoms is usually long, more than 4 years in one series.[158] The CSF protein is usually normal unless associated meningitis is present.[157, 158]

Epidermoid cysts may be located anterolateral or posterolateral to the brainstem. They tend to expand where

St. Louis: Mosby-Year Book, 1994.)

physical resistance is low and often burrow into crevices on the surface of the brain, ''dumbbell'' into the middle fossa (Fig. 25-20), or extend around the brainstem into the contralateral cistern. Their shapes are thus quite variable, and their surfaces tend to show fine cauliflower-like irregularity (Figs. 25-20 to 25-22).[158]

On CT, epidermoid cysts approximate CSF in density, and they are usually nonenhancing masses. However, hyperdense epidermoid cysts have been reported, as have enhancing borders, and small amounts of calcification are sometimes found in the periphery of the tumors.[159–163] Squamous cell carcinoma arising from an epidermoid cyst has been reported, and an enhancing component in an epidermoid cyst may suggest an associated malignancy.[164, 165] Perifocal edema is rarely observed in association with epidermoid tumors, and pressure erosion of the petrous apex is sometimes encountered.[20, 158, 159]

On MR imaging, epidermoid cysts tend to be relatively homogeneous. They are usually isointense or slightly hyperintense to CSF on T1-weighted images and are hyperintense to CSF on T2-weighted images (Fig. 25-21).[9, 166] Steady-state free precession images (FISP) improve the visibility of epidermoid cysts over conventional spin-echo images.[167] A thin capsule or fine tissue strands may be seen in some of the tumors.[168] Epidermoid cysts may resemble schwannomas, meningiomas, or chondromas by signal intensity criteria, but unlike the other tumors, they are nonenhancing. Their CT density also may help in the differentiation. Rarely, epidermoid tumors show reversed signal intensities and are hyperintense on T1-weighted images and hypointense on T2-weighted images (white epidermoids) (Fig. 25-22).[160, 169, 170]

An arachnoid cyst, also of CSF density and intensity, is difficult to differentiate from an epidermoid on both CT and MR imaging (Fig. 25-23).[171] An attempt to differentiate the two may be worthwhile because the symptoms of arachnoid cysts may be controlled by diuretics alone.[172] Arachnoid cysts, usually large masses, possess smoother surfaces than epidermoids, and on CT, intrathecal contrast may be used to differentiate their surface characteristics (Fig. 25-24).[145] CISS, FLAIR, and diffusion-weighted MR imaging sequences are of critical value in differentiating arachnoid cysts from epidermoids.[173–177] These new MR imaging techniques usually obviate the need for intrathecal contrast administration.

Cysticercosis is another diagnostic consideration in endemic areas (Fig. 25-25). In contrast to parenchymal and intraventricular cysts, which are separate from one another, cisternal cysticercal cysts are usually racemose, several centimeters in size, and lacking a scolex.[178] Such cysts in the CPA may cause symptoms suggestive of acoustic schwannoma. Because their fluid may be identical to CSF on CT and MR imaging, the presence of cysticercal cysts is sometimes suggested only

by focal cisternal widening.[178] They are seen better on MR imaging than on CT. The majority are detectable only on T1-weighted images, but T2-weighted images demonstrate the surrounding tissue reaction to greater advantage.[179]

Rarely, congenital cysts such as an epithelial cyst, a neurenteric cyst, or a craniopharyngioma, found in the CPA may show CT densities and MR signal intensities atypical of uncomplicated cysts.[180–187] Very rarely, a totally cystic schwannoma may also simulate an epidermoid cyst.[187]

Lipomas, more likely in the midline than in the CPA, show negative Hounsfield unit numbers on CT and isointensity to fat on MR imaging (Figs. 25-26 and 25-27).[27, 188, 189] Dermoid cysts show fatty density or signal intensity and may also contain teeth and peripheral calcifications.[157, 188] Fat-suppression techniques may be used for confirmation.[12] Because most authors recommend conservative management of CPA and IAC lipomas, a correct preoperative diagnosis is important.[190, 191]

Nonacoustic Posterior Fossa Schwannomas

The nonacoustic schwannomas resemble acoustic schwannomas in appearance but not in location.[192] Thus it is important to note the precise location of a schwannoma-appearing tumor and to search carefully for any associated foraminal changes in the skull base. Acoustic schwannomas account for 95% of all intracranial schwannomas, and trigeminal schwannomas are in a distant second place.[130, 192]

Trigeminal schwannomas may arise intradurally from the nerve root in the CPA and Meckel's cave or extradurally from the gasserian ganglion in the middle cranial fossa.[193–196] They also may involve both the posterior and the middle fossa (Figs. 25-28 and 25-29).[193, 195–197] The tumor is centered anteromedial to the IAC, and careful study often shows that a portion of the tumor extends through the porus trigeminus into Meckel's cave.[20, 195] The foramen ovale or the foramen rotundum also may be enlarged. Compared with acoustic schwannomas, trigeminal schwannomas are more likely to contain cystic components and are

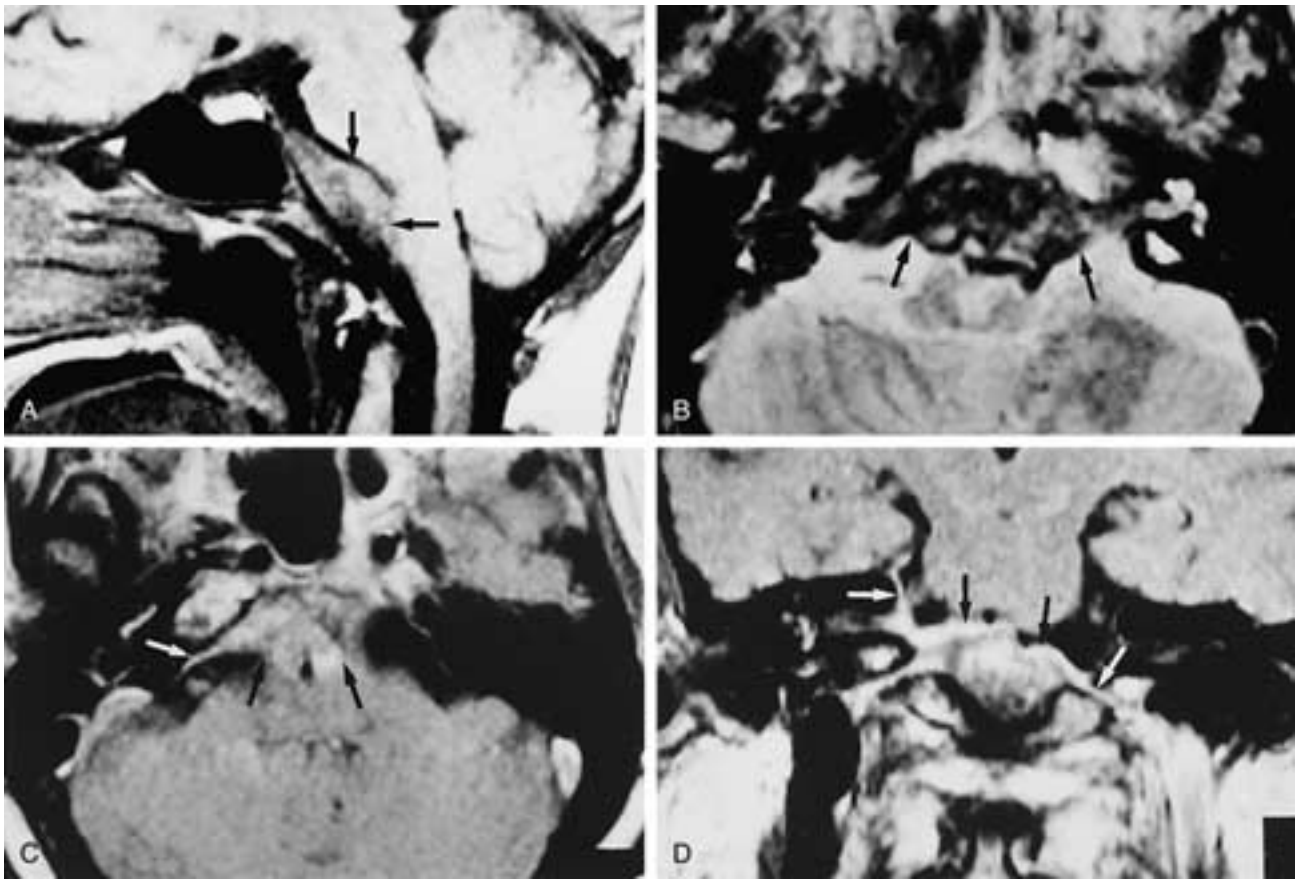

FIGURE 25-19 Idiopathic hypertrophic pachymeningitis. **A**, Sagittal T1-weighted image. **B**, T2-weighted image. **C**, Gadolinium T1-weighted image. **D**, Coronal gadolinium T1-weighted image. The mass (*black arrows*) is extraaxial and dural-based on the clivus and posterior petrous surface. It is slightly inhomogeneous and hypointense on T1-weighted images (**A**) and inhomogeneous in intensity on T2-weighted images (**B**), with mild inhomogeneous enhancement after contrast administration (**C** and **D**), except for dural tails (*white arrow*), where enhancement is more intense. The patient is a 50-year-old woman who was found to have a rubbery, hypovascular prepontine mass on transtemporal exploration, and had well-formed granulomas and chronic inflammation on histopathologic examination. No organisms were found on stains and cultures. (Courtesy of Dr. Robert K. Jackler.) (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)

FIGURE 25-20 CPA epidermoid. **A** and **B**, T1-weighted axial and sagittal images after gadolinium administration. The CPA mass extending to the prepontine cistern is isointense to CSF and shows no enhancement. **C**, T2-weighted image. The tumor, with irregular, cauliflower-like margins, is isointense to CSF, as in T1-weighted images, and is compressing the fourth ventricle. The IAC is normal. **D**, FLAIR image. In this sequence the epidermoid has heterogeneous hyperintense foci, enabling differentiation of an epidermoid from an arachnoid cyst in this case.

thus more varied in appearance (Fig. 25-29).[20, 197] On CT they may be isodense or slightly hypodense or show mixed iso-hypodensity. They exhibit well-circumscribed enhancement that may or may not be homogeneous.[197] On MR imaging, their signal intensities are similar to those of acoustic schwannomas.[9, 194, 197] In most cases they are better localized and characterized on MR imaging than on CT.[9]

Facial nerve schwannomas are rare tumors that may arise from any segment of the facial nerve. When arising in the CPA or the IAC, they usually first cause sensorineural hearing loss rather than facial palsy, and thus may be both clinically and radiologically indistinguishable from acoustic schwannomas (Figs. 25-30 to 25-32).[198–200]

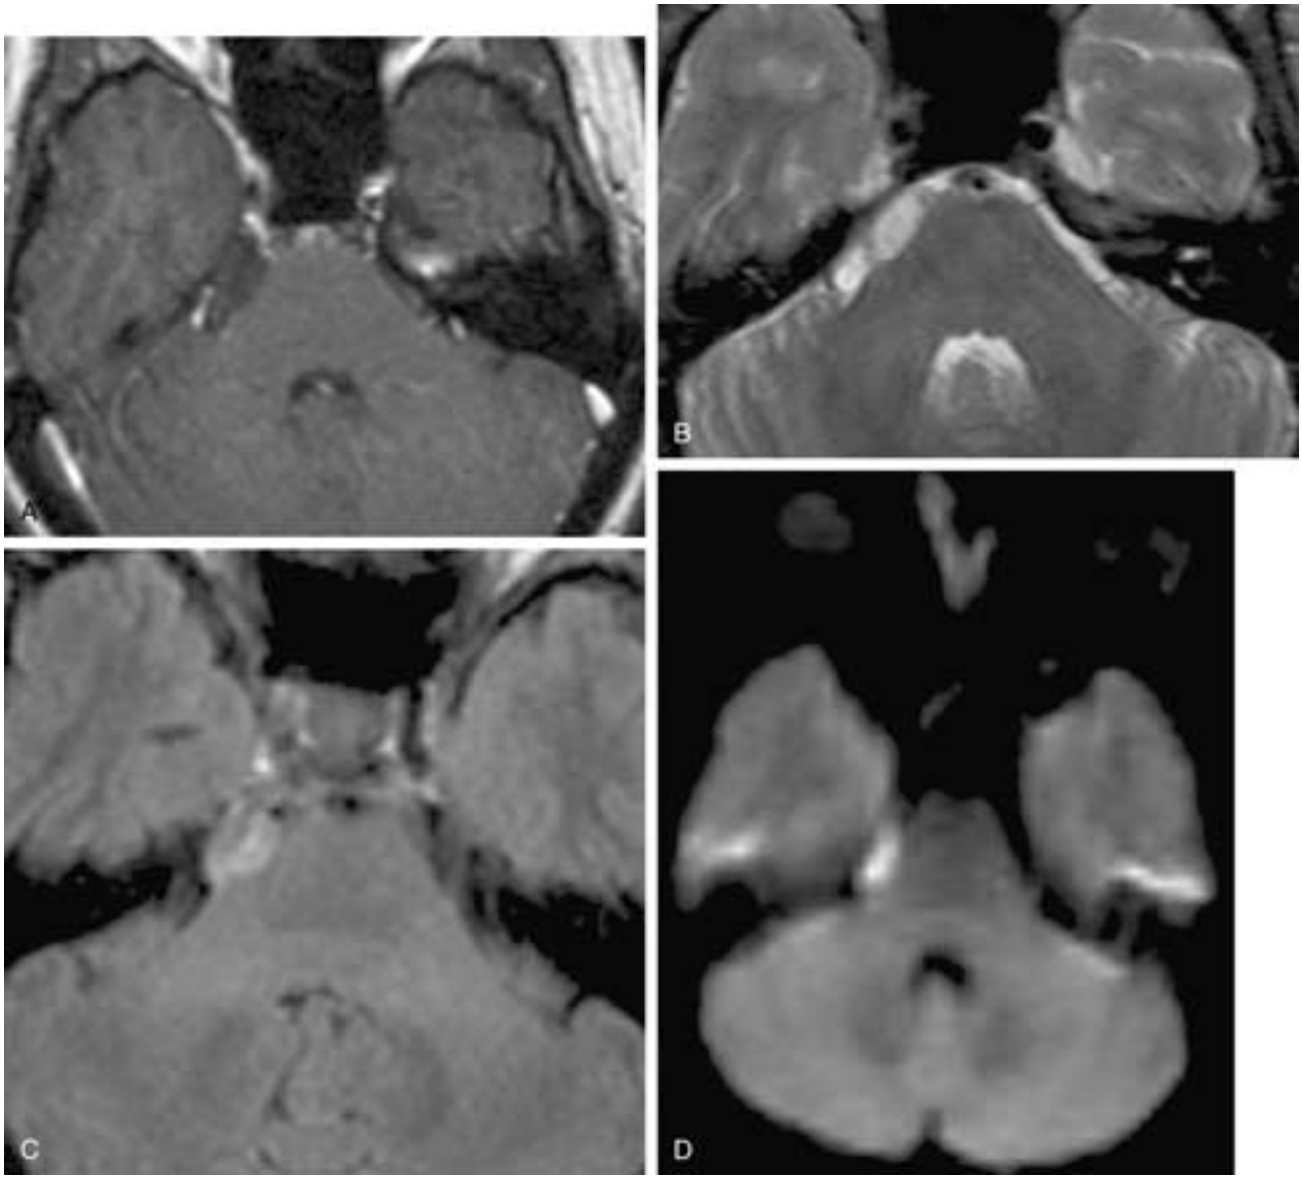
Similarly, glossopharyngeal, vagus, and spinal accessory schwannomas cause specific neural deficits only when they occur within the jugular foramen (Figs. 25-33 and 25-34).[201, 202] When arising within the posterior fossa, they may attain considerable size and first appear instead with

Copyright © 2003, Mosby, Inc. All rights reserved.

predominantly acoustic or cerebellar signs and symptoms.[202, 203] Hence they also should be considered in the differential diagnosis of acoustic schwannomas. Foraminal widening, if present, aids immensely in the diagnosis.[203] A correct preoperative diagnosis averts the use of the translabyrinthine approach, which would destroy residual hearing.[204]

Vascular Lesions

Vascular lesions of the CPA are rare, but a number of them may clinically mimic neoplasms and thus assume differential diagnostic importance on CT and MR imaging. Vertebrobasilar dolichoectasia (VDB), or elongation and dilatation of the vertebrobasilar artery, is probably the most common vascular lesion associated with compressive symptoms of the posterior fossa cranial nerves. Elongation of the basilar artery is considered present if any portion of it extends lateral to the margin of the clivus or the dorsum sellae or if the artery bifurcates above the plane of the suprasellar cistern (Figs. 25-35 and 25-36). Ectasia is diagnosed if the diameter of the basilar artery is greater than 4.5 mm on CT.[205] If angiography is necessary in a patient with a basilar artery more than 1.5 cm in diameter, a nonselective digital subtraction study is advised.[206] The larger volume of the vessel prevents adequate washout of the contrast, and stagnation can occur with layering along the posterior wall of the vessel. The contrast may cover the exit points of small arteries supplying the pons and limit flow to these important vessels. An infarct can result.



VIEW IMAGE

FIGURE 25-21 Epidermoid. **A** and **B**, T1-weighted postgadolinium and T2-weighted images. A small mass is seen adjacent and anterior to the right fifth nerve. The lesion is isointense to CSF in spin echo sequences and does not enhance. **C**, FLAIR image shows hyperintensity relative to CSF. **D**, Diffusion-weighted image. The epidermoid has hyperintense signal due to restricted proton motion, differentiating it from an arachnoid cyst.

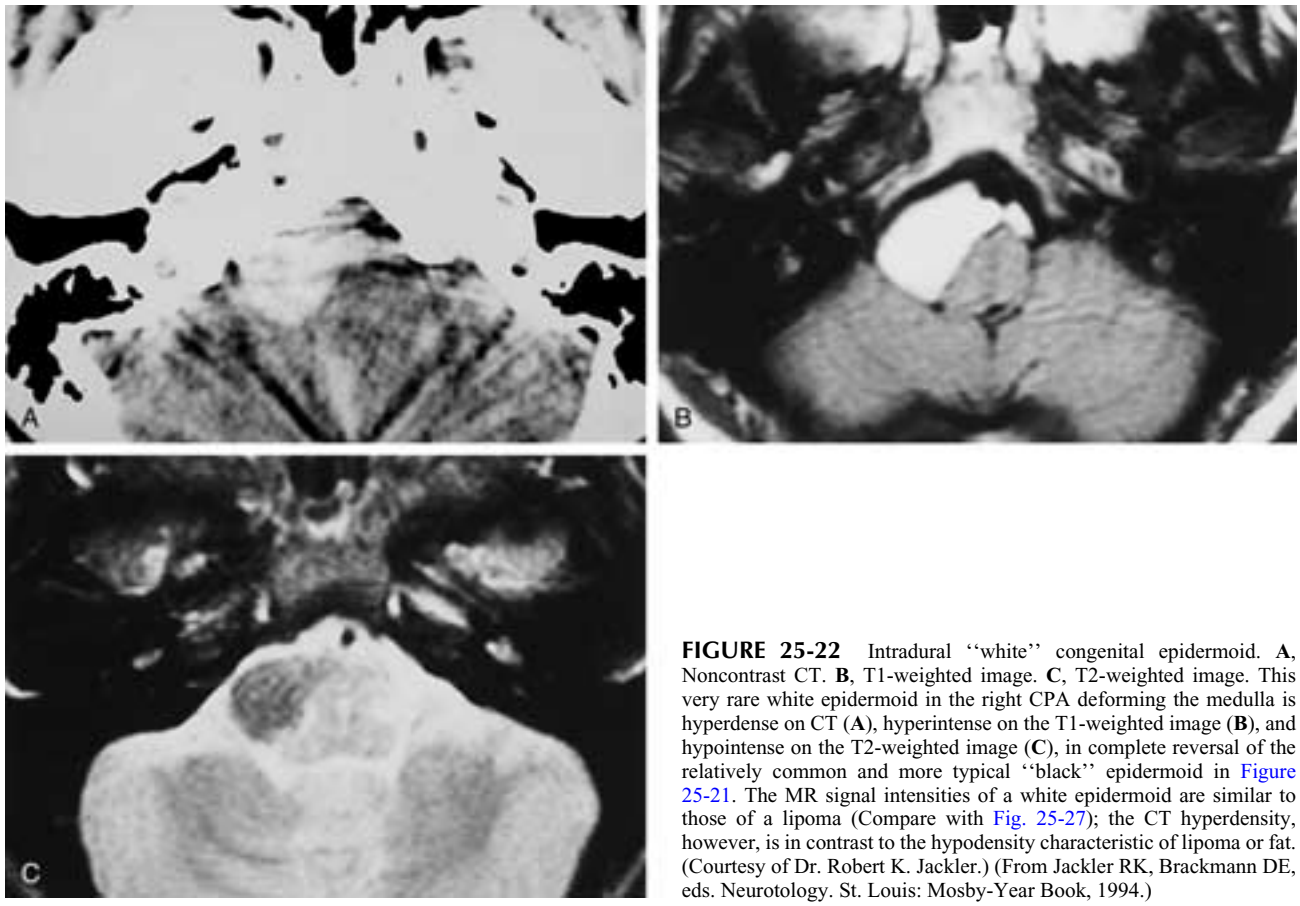

FIGURE 25-22 Intradural ''white'' congenital epidermoid. **A**, Noncontrast CT. **B**, T1-weighted image. **C**, T2-weighted image. This very rare white epidermoid in the right CPA deforming the medulla is hyperdense on CT (**A**), hyperintense on the T1-weighted image (**B**), and hypointense on the T2-weighted image (**C**), in complete reversal of the relatively common and more typical ''black'' epidermoid in Figure 25-21. The MR signal intensities of a white epidermoid are similar to those of a lipoma (Compare with Fig. 25-27); the CT hyperdensity, however, is in contrast to the hypodensity characteristic of lipoma or fat. (Courtesy of Dr. Robert K. Jackler.) (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)

VIEW IMAGE

The vertebrobasilar artery is superbly demonstrated on MR imaging by its signal void, and magnetic resonance angiography (MRA) gives an even more graphic depiction (Fig. 25-37). However, the CSF flow phenomenon may mimic a basilar artery aneurysm, and a thrombosed or partially thrombosed dolichoectatic basilar artery may simulate an extraaxial tumor.[207, 208]

The most common symptoms reported are those associated with the facial nerve, such as hemifacial spasm and facial paresis.[206, 209] The second most common symptom is trigeminal neuralgia.[206] Other cranial nerves that have been affected include the oculomotor, abducens, acoustic, glossopharyngeal, and vagus.[206, 210, 211] Disabling positional vertigo resulting from vascular compression of the acoustic nerve has been described in a series of patients without specific reference to VBD.[212]

Patients with VBD may or may not be symptomatic, but the incidence of symptoms does appear to correlate with the degree of tortuosity.[213, 214] In general, symptomatic patients with elongated but undilated vertebrobasilar arteries are much more likely to have single cranial nerve involvement (Figs. 25-35, 25-37); those with elongated and dilated arteries are much more likely to have combinations of multiple compressive cranial nerve deficits, compressive and ischemic central nervous system deficits, and hydrocephalus (Fig. 25-36).[206] The compressive symptoms can in some cases be relieved by microvascular decompression.[215–217] Preoperative angiography may be of predictive value, but because of its invasive nature it has generally been replaced by MR imaging or MRA.[218–220] Neurovascular conflict imaging protocols have evolved and include high-resolution 3D time-of-flight (TOF), 3D-CISS, and T2-weighted sequences. These volume-acquired sequences allow for reconstructions and reformation in multiple planes and facilitate identification of nerve vessel conflicts in most cases.[221–227]

Vascular loop, a loop of the AICA, has been implicated in acoustic nerve symptoms, in particular, vertigo.[210, 212, 228] On its normal course from the basilar artery to the cerebellum, the AICA forms a loop under, over, or between the facial and acoustic nerves as it gives rise to the auditory artery.[229] The loop may be located in the cistern or at the porus, or it may be found, in up to 19% by microdissection and in 22% by gas-CT cisternography, in the IAC.[229, 230] Thus the mere finding of an AICA loop, intracanalicular or otherwise, does not establish it as the cause of symptoms. Furthermore, vascular compression of a nerve, even to the point of grooving it, may fail to cause symptoms in some patients.[231] To produce symptoms, the cross-compression may have to coincide with the glial–Schwann cell junction.[229] Thin-section T2-weighted (Fig. 25-38) and CISS images have proven to be very sensitive and are utilized as a noninvasive replacement for gas-CT cisternography.[221–227, 232]

Berry aneurysms of the AICA are quite rare, representing less than 1% of intracranial aneurysms (Fig. 25-39).[233] They have often carried a preoperative diagnosis of acoustic tumor, and of 22 reported patients, 16 had acoustic and 14

Copyright © 2003, Mosby, Inc. All rights reserved.

had facial nerve signs and symptoms, and 14 had subarachnoid hemorrhage.[233] Dense homogeneous enhancement may be a clue, and dynamic CT may contribute by showing rapid opacification. MR imaging is diagnostic if a signal void from rapidly flowing blood is demonstrated in the aneurysm. MRA may be useful, but angiography is definitive.

Giant aneurysms are those exceeding 2.5 cm in diameter (Fig. 25-40).[20] They may originate from the vertebrobasilar artery or from one of its branches and extend into the CPA as a mass lesion. They rarely cause subarachnoid hemorrhage, and most commonly they are partially thrombosed.[20, 234] On CT a partially thrombosed aneurysm shows an enhancing rim with an isodense, nonenhancing mural thrombus and an enhancing lumen. A calcific rim may be present. A nonthrombosed aneurysm shows homogeneous enhancement, and a thrombosed one shows an enhancing rim with an isodense, nonenhancing center.[20] MR imaging demonstrates a flow void in the patent lumen, laminated thrombus of varying signal intensities, and sometimes a low signal intensity rim.[235–237]

Superficial siderosis (SS) of the acoustic nerves, or pial siderosis, is not a vascular lesion per se but instead is the result of chronic capillary or venous subarachnoid hemorrhage such as may be caused by an ependymoma.[238, 239] It is a long-recognized, rare pathologic entity, the antemortem noninvasive diagnosis of which has become possible with the advent of high-field MR imaging (Fig. 25-41).[238, 239] It consists of intracellular and extracellular deposition of hemosiderin in the leptomeninges, subpial tissue, spinal cord, and cranial nerves. The acoustic nerve, with its long glial-lined segment, is especially vulnerable to the toxic effects of hemoglobin and hemosiderin deposition. The clinical findings include hearing loss, cerebellar dysfunction, pyramidal tract signs, and, at times, progressive mental deterioration. The CSF is xanthochromic and rich in protein.

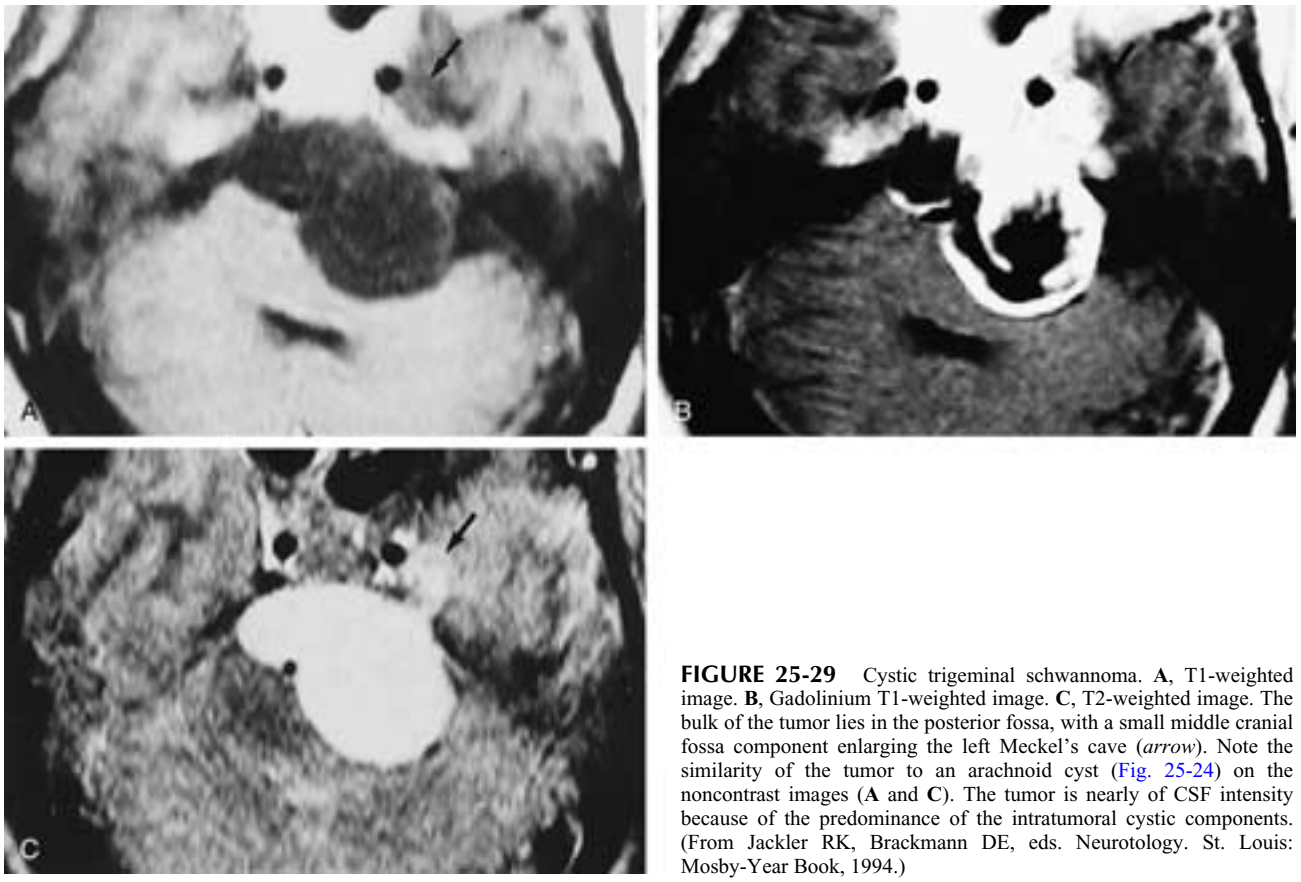

FIGURE 25-29 Cystic trigeminal schwannoma. **A**, T1-weighted image. **B**, Gadolinium T1-weighted image. **C**, T2-weighted image. The bulk of the tumor lies in the posterior fossa, with a small middle cranial fossa component enlarging the left Meckel's cave (*arrow*). Note the similarity of the tumor to an arachnoid cyst (Fig. 25-24) on the noncontrast images (**A** and **C**). The tumor is nearly of CSF intensity because of the predominance of the intratumoral cystic components. (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)

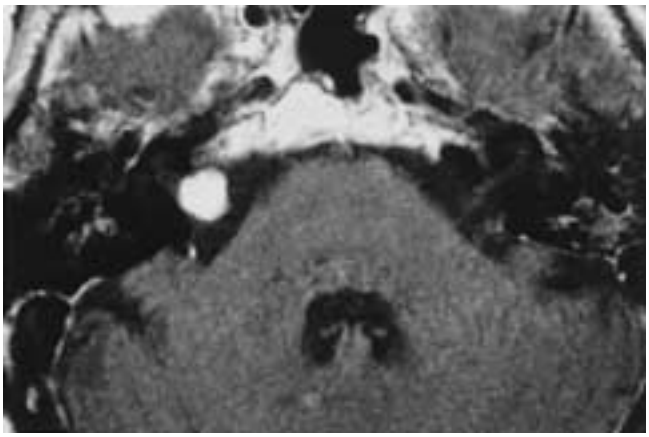
VIEW IMAGE

On high-field MR imaging, the T2-weighted images show marked hypointensity of the pial and arachnoid membranes and the acoustic nerves (Fig. 25-41).[240]

A hemangioma or vascular malformation of the acoustic or facial nerves appears as an intracanalicular tumor. Some may contain intratumoral bone spicules best seen on high-resolution CT with bone algorithm (Figs. 25-42 and 25-43).[241] On MR imaging they tend to be more hyperintense on T2-weighted images than are acoustic schwannomas (Fig. 25-44), and they may invade the adjacent temporal bone.[241, 242]

Arteriovenous malformations (AVMs) in the CPA are exceedingly rare, but extracerebral AVMs, predisposed to subarachnoid bleeding, may occur in this location.[243] Dilated enhancing vessels may be seen on CT, and serpentine hypointense loops are found on MR imaging.[20] Angiography provides definitive visualization of the feeding arteries and draining veins. AVMs, which are congenital, should be distinguished from dural arteriovenous fistulas (DAVFs), which are acquired (Fig. 25-45).



VIEW IMAGE

FIGURE 25-30 CPA facial schwannoma. Gadolinium T1-weighted image. This isointense, rounded, extraaxial tumor is centered at the porus acousticus. The lesion enhances intensely and is indistinguishable from acoustic schwannoma (Fig. 25-9). (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)

Petrous Bone Lesions

These are quite numerous and will be discussed in greater detail in a following section of this chapter. However, they should be considered in the differential diagnosis of CPA masses; for example, an exophytic growth from a chondrosarcoma may be mistaken for a meningioma (see Fig. 25-83).[244]

Paragangliomas

These tumors, discussed in greater detail in a following section, have a different presenting symptom complex and are not usually confused clinically with acoustic schwannomas. However, they may have intracranial extradural or

FIGURE 25-34 Jugular foramen schwannoma. **A** and **B**, Axial and coronal T1-weighted postgadolinium images. The large tumor in the left jugular fossa is extending inferiorly. It shows avid enhancement. **C**, T2-weighted coronal image depicts the extracranial portion of the tumor, which is hyperintense to gray matter. **D**, CT bone windows, coronal image. Expansion of the jugular foramen is symmetric, and the margins are well defined. (Contrast with Figs. 25-66, 25-67, 25-68, and 25-69.)

transdural extensions in the posterior fossa, which on CT or MR imaging mimic schwannomas or meningiomas. Identifying their precise location and associated bone changes should help avoid misdiagnoses.

Intraaxial Tumors

A detailed description of these and other primary lesions of the brain is beyond the scope of this section. Some intraaxial tumors occasionally occur in the CPA and must be considered in the differential diagnosis. Intraaxial posterior fossa tumors may arise from the brainstem, the cerebellum, or the fourth ventricle. Tumors of the brainstem include those from the medulla, the pons, the midbrain, and the cerebellar peduncles, and they are mainly astrocytomas occurring in children or young adults (Fig. 25-46).[245–247] On CT they are isodense or hypodense, and on MR they are hypointense on T1-weighted images and hyperintense on T2-weighted images.[246] They show little enhancement.[126] The brainstem is usually enlarged, the fourth ventricle is posteriorly displaced, and there may be exophytic growth extending into the cistern.[245] The diffuse fibrillary high-grade astrocytomas carry a poor prognosis, and the smaller and more localized pilocystic astrocytomas carry a better prognosis.[246]

Tumors of the cerebellum may arise from the vermis or the hemisphere. Vermian tumors, principally medulloblastomas (an embryonal tumor) in childhood, rarely may extend to the CPA. They are hyperdense and enhancing. Hemispheric tumors are most commonly hemangioblastomas and

FIGURE 25-36 VDB. **A**, Sagittal T1-weighted image. The dilated, tortuous basilar artery (*curved arrow*) shows peripheral laminar hyperintensity caused by very slow flow or thrombi and central moderate intensities resulting from moderately slow flow within the patent lumen. A normal flow void is seen in the undilated proximal and distal arteries (*straight arrows*). **B**, Gradient-echo image. Flowing blood appears hyperintense on such images. The basilar artery (*curved arrows*) shows marked fusiform dilatation and marked tortuosity. Signal intensities in such dilated arteries are often complex because of the presence of thrombi of varying age and flow of varying velocity. Similarly complex intensity patterns also may be found in giant aneurysms, although the latter lesions are rounded or ovoid rather than fusiform. (Courtesy of Dr. William P. Dillon.) (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)

metastases in adults and astrocytomas in young adults or children. All three lesions may be either enhancing solid masses or cystic masses with solid components. Hemangioblastomas may be multiple and associated with von Hippel-Lindau disease. Their solid components are characteristically hypervascular on angiography or MR imaging.[248, 249]

From the fourth ventricle arise the ependymoma and choroid plexus papilloma (Figs. 25-47 to 25-49). They may cause CPA symptoms when growing through the foramen of Luschka.[250–254] Naidich et al. found extension to the CPA in 7 of 12 ependymomas, 2 of 6 in a group of medulloblastomas and a cerebellar sarcoma, 1 of 23 astrocytomas, and 1 of 8 hemangioblastomas.[128]

Ependymomas tend to calcify. The calcified portions are variable in density and enhancement.[126] Papillomas are well-defined lesions, slightly hyperdense, and moderately enhancing.[126] Both tumors are nearly isointense to brain on T1-weighted images and mildly hyperintense on T2-weighted images (Figs. 25-47 and 25-49).[252–255] The intraaxial tumors are generally nearly isointense on T1-weighted images and hyperintense on T2-weighted images, and except for any calcifications, they are better demonstrated on MR imaging than on CT.[256, 257] Lym-

phoma, much more common in the 1990s in both immunosuppressed and immunocompetent patients, also may occur in the CPA (Fig. 25-50).[150, 258–260] Nonneoplastic brain lesions such as multiple sclerosis (Fig. 25-51) and infarct (Fig. 25-52), of course, may be occasionally encountered in the investigation of CPA symptoms. Primitive neuroepithelial tumors (PNETs) can be seen in the CPA and should be part of the differential diagnosis. These are densely cellular tumors with imaging characteristics similar to those of PNETs in other sites. They exhibit hypointense signal on T1-weighted images and iso- to hypointense signal on T2-weighted images with moderately intense heterogeneous contrast enhancement (Fig. 25-53).[261]

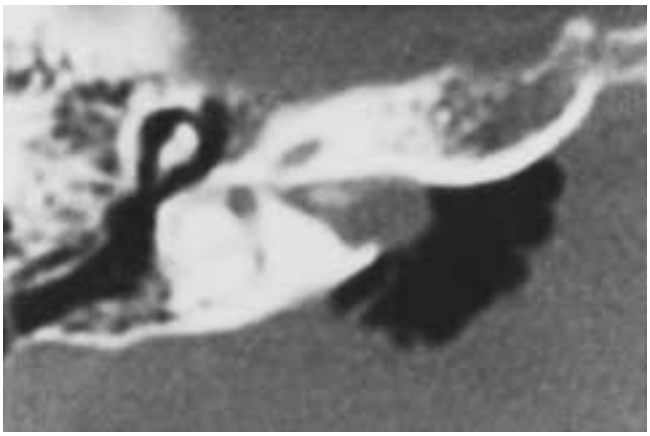
No abnormality is apparent. **B**, T2-weighted image. A thin layer of hypointensity from pial and subpial deposition of hemosiderin is visible on the pons, cerebellum, and acoustic nerves (*arrows*). A thin layer of hypointensity is also present on the inferior surfaces of the cerebral hemisphere (not illustrated). Hypointensity of the dentate nuclei (*curved arrow*) may be physiologic. (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)

Intracanalicular Lesions

The differential diagnoses of intracanalicular lesions differ slightly from those of CPA masses (Box 25-1) as follows:

1. Acoustic schwannomas are by far the most common lesions, representing over 90% of the intracanalicular lesions (Figs. 25-3 and 25-4).[36, 105]
2. Facial schwannomas (Fig. 25-31) are often clinically and radiologically identical to acoustic schwannomas, and they may extend into the labyrinthine facial nerve canal.[200, 262]
3. Meningiomas are often cited but seldom are fully documented.[263] An intracanalicular meningioma may be indistinguishable from a schwannoma unless accompanied by hyperostosis or a dural tail.
4. Intracanalicular vascular tumors tend to cause a greater degree of nerve deficits and more commonly result in facial nerve symptoms than do acoustic schwannomas of comparable size.[264, 265] Some of them contain intratumoral bone spicules discernible on high-resolution CT with a bone algorithm (Figs. 25-42 and 25-43). On MR imaging they tend to be slightly more hyperintense than the typical schwannoma (Fig. 25-44), and they may invade the adjacent petrous bone.[241, 242]
5. Intracanalicular metastases are rare but may be suspected from a short duration of symptoms, facial weakness, a known history of malignancy, and a rapid growth rate on serial studies (Figs. 25-18, 25-54 and 25-55).[266–268] They may be bilateral.[268]
6. Lipomas show fatty CT density and MR intensities (Figs. 25-26, 25-27) and may be confirmed by fat suppression techniques.[189, 190, 269]
7. Lymphomas may be neural or leptomeningeal, primary (Fig. 25-56) or systemic (Fig. 25-57).[259]
8. Osteoma (Fig. 25-58).
9. Melanoma, typically hyperintense on T1-weighted images and hypointense on T2-weighted images when intraocular, may not follow such a pattern when intracranial (Figs. 25-17 and 25-55).[153, 270]
10. Glioma.[24, 39]

    Note: Melanoma and glioma are very rare IAC neoplasms.



VIEW IMAGE

Rarely, a hamartoma of the acoustic nerve has been found at autopsy or encountered in clinical practice.[271, 272] Other nonneoplastic conditions include (1) intracanalicular loop of the AICA (Fig. 25-38), (2) aneurysm arising from the AICA (Fig. 25-39), (3) arachnoid adhesions, (4) neuritis (Fig. 25-59), and (5) chronic inflammation (Fig. 25-60).[79, 191, 193–195, 234–237] Focal neuritis (Fig. 25-59) can have an appearance treacherously similar to that of an intracanalicular schwannoma (Fig. 25-3). A rare cause of nonneoplastic hypertrophic neuropathy, Dejerine-Sottas disease, can also result in thickening and abnormal contrast enhancement of multiple cranial nerves including the facial and vestibulocochlear nerves (Fig. 25-61).[273, 274]

VIEW IMAGE

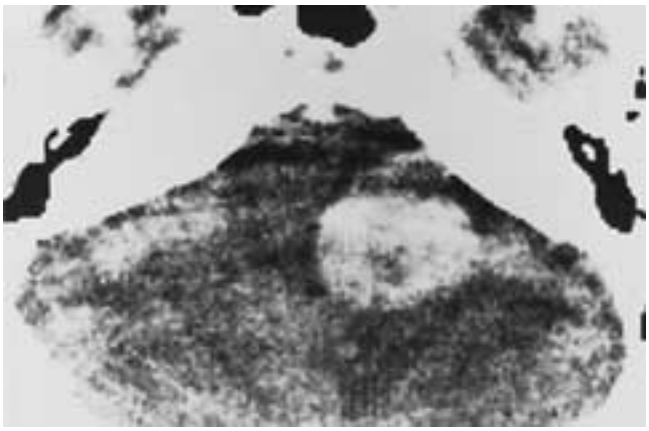
Because intracanalicular lesions are frequently only 3 or 4 mm in size, excellent technique is required for their demonstration. At MR imaging, this requires T1-weighted contiguous 2 mm sections and the use of intravenous gadolinium. Images less than 1 mm can be obtained with the use of 3D gradient-echo sequences.[85] High-resolution, thin-section, T2-weighted, 3D-CISS MR imaging, by outlining the contours of the cranial nerves surrounded by CSF, has detected small tumors without the use of intravenous paramagnetic contrast (Fig. 25-2).[17, 275]



VIEW IMAGE

FIGURE 25-48 CPA choroid plexus papilloma. Postcontrast CT scan. The tumor is located at the foramen of Luschka. It is more sharply defined than an ependymoma. Like a giant aneurysm, it is detached from the petrous bone, in contrast to schwannomas and meningiomas.

Summary

In summary, the three most common extraaxial masses in the CPA are acoustic schwannoma, meningioma, and congenital epidermoid cyst. They are relatively consistent in location, configuration, CT density, MR intensity, and enhancement patterns (Table 25-3). The same may be said for the rarer nonacoustic posterior fossa schwannomas and the various vascular lesions. If one analyzes each lesion systematically, takes into consideration the clinical information, and avoids the traps set by the occasional extradural or intraaxial lesions intruding into the CPA, a correct preoperative diagnosis can be reached in an overwhelmingly large percentage of the cases.

PARAGANGLIOMAS AND JUGULAR FORAMEN TUMORS

Incidence, Origin, and Terms

Paraganglioma is the second most common tumor involving the temporal bone and is the most common in the middle ear.[20, 276] In the branchiomeric family of paraganglia, two groups are by location closely related to the jugular

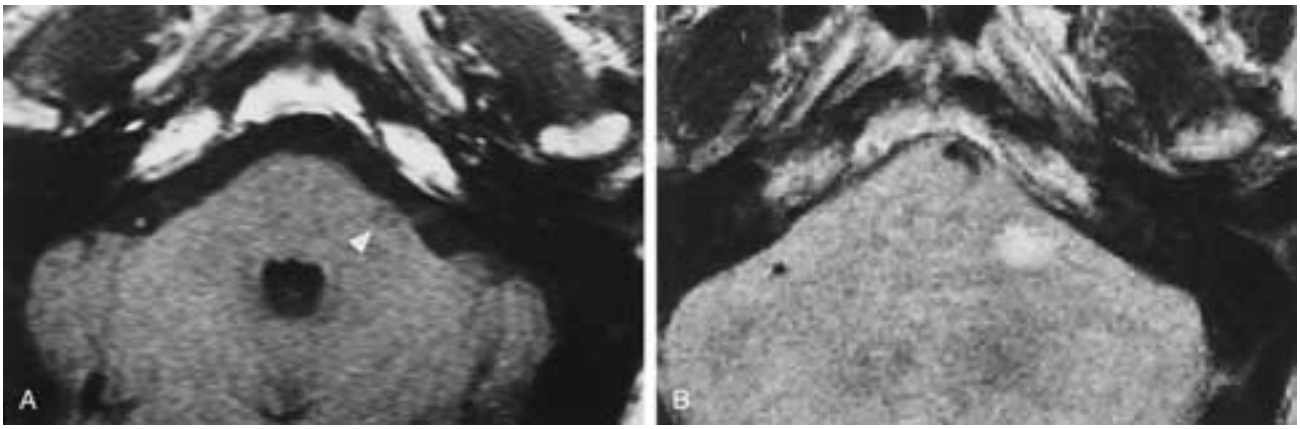
Considerable decrease in thickening and enhancement has occurred since the initial study (**B**), with now only residual enhancement in the cochlear nerve. Lack of clinical improvement led to exploration by the middle fossa approach; no tumor was found. (Courtesy of Dr. Michael J. O'Leary.) (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)



VIEW IMAGE

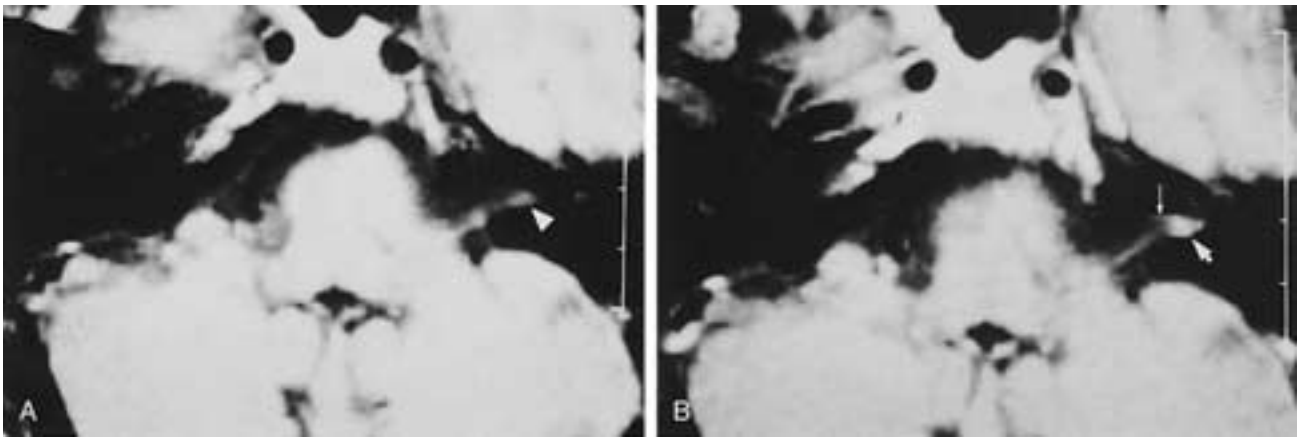
jugulare.[278, 279] The term *glomus tympanicum tumor* was introduced by Alford and Guilford when they noted that those arising ''away from the jugular bulb, in the middle ear, along the course of Jacobson's nerve'' had a better prognosis than those arising ''in the area of the jugular bulb.''[280, 281] Glasscock et al. clarified the definition so that glomus tympanicum tumors include those in the tympanic cavity and the mastoid, and glomus jugulare tumors include those involving the jugular bulb and the base of the skull.[282] Glomus vagale tumors (vagal paragangliomas) arise from the intravagal paraganglia at or below the skull base and are primarily parapharyngeal masses (see Chapter 38).



VIEW IMAGE

Clinical Features

Paragangliomas occur in women three times as often as in men. When first seen, two thirds of the patients are in their fourth and fifth decades of life. The tumors may be bilateral, and other tumors such as carotid body tumors may coexist. Up to 10% of the patients may have multiple tumors.[283] Normally locally infiltrating, these tumors rarely may metastasize. Up to 10% are accompanied by malignant tumors in other organ systems. Very rarely, larger paragangliomas may secrete norepinephrine (as in pheochromocytomas) or, less often, ACTH, serotonin, calcitonin, and dopamine.[284] Occasionally, paragangliomas have been found to be familial.[285]

Paragangliomas can grow laterally, producing otologic symptoms (conductive hearing loss, pulsatile tinnitus, or a retrotympanic mass), and medially, resulting in the jugular foramen (or Vernet's) syndrome, consisting of glossopharyngeal, vagus, and spinal accessory deficits.[286, 287] However, in both tympanicum and jugulare tumors, otologic symptoms predominate and cranial nerve palsies appear only in a minority of the patients.[286] Clinical differentiation between the two groups is therefore impossible in the majority of cases unless a small tympanicum tumor is circumferentially visible.

In addition to involvement of the ninth through eleventh cranial nerves as the tumor enlarges, the hypoglossal nerve may be compromised in the region of the hypoglossal canal (Collet-Sicard's syndrome) and the facial nerve in its mastoid segment.[287, 288] Involvement of the carotid canal may cause Horner's syndrome, extension to the cavernous sinus will cause a cavernous sinus syndrome, and extension to the posterior fossa may cause brainstem and cerebellar signs and symptoms and hydrocephalus.[286, 287]

Vagal paragangliomas (glomus vagale tumors) develop inferior to the skull base, usually appearing as masses in the neck or the pharynx, and often involve the cranial nerves. They do not cause pulsatile tinnitus or conductive hearing loss, and they may or may not involve the temporal bone.[289]

High-resolution CT with bone detail is the most helpful imaging study for relating tumor extent to surgical landmarks and determining the surgical approach (Figs. 25-63 to 25-68). Angiography can be valuable in the differential diagnosis when the identity of a tumor is not obvious at sectional imaging, and angiography is frequently done to provide ac-

FIGURE 25-64 Large glomus tympanicum tumor. Axial CT. Fisch type A tumor too large to be differentiated from glomus jugulare tumor by otoscopy. CT, showing an intact jugular plate, definitely excludes a glomus jugulare tumor. The tumor, extending to the protympanum and obstructing mastoid drainage, is not distinguishable from other benign middle ear tumors by CT. All such tumors can be resected by the transmastoid approach. Angiography is not necessary.

cess for preoperative embolization (Figs. 25-69 and 25-70). MR imaging is helpful in soft-tissue localization and characterization of the tumor (Figs. 25-71 to 25-75).[8, 290, 291]

Growth Pattern and CT Findings

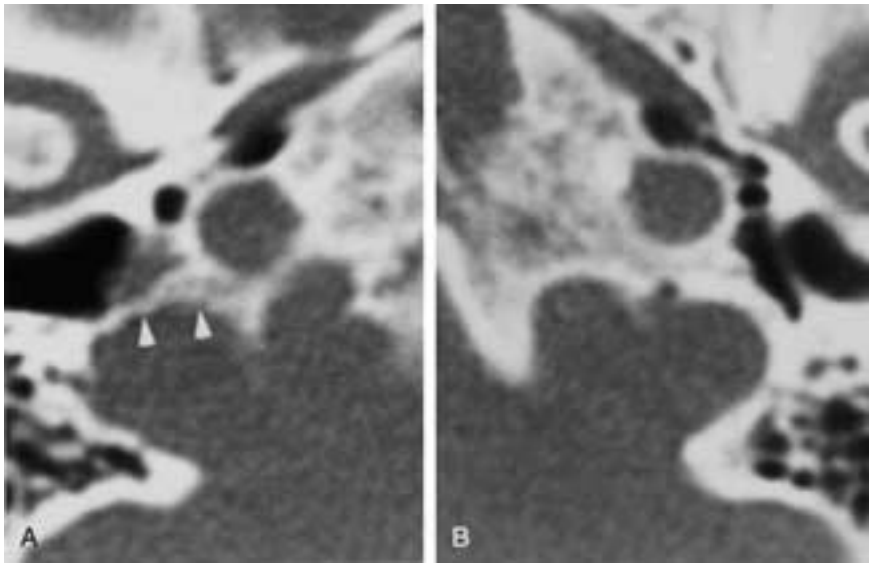
Paragangliomas grow slowly and rarely metastasize.[283] Although localized bone destruction around the jugular foramen is common, extensive destruction by expansion occurs relatively late. Paragangliomas tend to grow along the planes of least resistance by following preexisting pathways in the temporal bone (i.e., fissures, air cell tracts, vascular channels, and foramina) (Figs. 25-71 and 25-74).[292, 293] Tumors commonly descend through the jugular vein (Fig. 25-76), and central nervous system invasion may ultimately cause death.[292]

When first diagnosed, a paraganglioma may vary from a few millimeters in diameter and easily resectable to 10 cm or larger and life-threatening (Figs. 25-63 and 25-77). The CT appearance of paragangliomas is therefore highly variable. Because paraganglia are located along the nerves of Jacobson and Arnold, the earliest findings of jugulotympanic paragangliomas are along the course of these two nerves (Figs. 25-62 to 25-65 and 25-74).[294]

Glomus tympanicum tumors tend to produce symptoms early, so that when first seen, they are often well-defined intratympanic soft-tissue masses without bone involvement (Fig. 25-63).[295, 296] They may extend into the external auditory canal, but often even when filling the tympanic cavity they leave the ossicles intact.[296]

Because of the proximity of the hypotympanum to the jugular fossa, a large percentage of paragangliomas involve both regions by extending through the jugular plate (Figs. 25-65 to 25-68 and 25-74).[294, 297] Early irregular demineralization is thus often first found in the jugular plate or in the lateral portion of the caroticojugular spine (Figs. 25-65 and 25-66). The jugular plate may be involved early by tumors originating from paraganglia located in the inferior tympanic canaliculus. More extensive destruction extends from around the pars vascularis and beyond (Fig. 25-66). The bone changes are irregular, and the margins are indistinct and may be described as ''moth-eaten.''[298] Further destruction extends medially to the pars nervosa and the petrooccipital fissure, anteriorly to the vertical and then the horizontal carotid canal, and posteriorly along the sigmoid sulcus to the transverse sulcus. The infralabyrinthine compartment is frequently destroyed, but superior tumor extension is often slowed by the dense bone of the otic capsule (Figs. 25-66 and 25-67). An intratympanic tumor may spread into the mastoid, and vice versa, the protympanum, and less often into the epitympanum (Fig. 25-64).

An infralabyrinthine soft-tissue mass is common, extending either intraluminally down the internal jugular vein or along the carotid sheath, frequently to the C2-3 level or even lower, appearing as an enhancing mass on CT (Fig. 25-76). Further posterior extension of tumor may displace the dura inward or grow through the dura to involve the cerebellum (Figs. 25-68 and 25-77). Very large tumors may also destroy



VIEW IMAGE

FIGURE 25-66 Glomus jugulare tumor. CT. **A**, Axial image shows demineralization of the bony margins of the jugular foramen on the right side (*black arrows*). There is demineralization of the fine cortical line usually demonstrated along the lateral aspect of the vascular portion of the jugular foramen. Compare with the intact cortical plate on the opposite side (*white arrow*). Note the demineralization of the bony wall separating the carotid canal from the jugular foramen. **B**, Blown-up axial image shows the demineralization of the lateral cortical plate (*arrowhead*), as well as slight demineralization of the bony plate between the carotid canal and the jugular foramen (*white arrow*). Note the proximity of the demineralized bone to the vertical section of the facial nerve canal (*black arrow*). **C**, Axial image enlarged through the normal side shows the intact white cortical line (*arrow*) along the lateral aspect of the jugular foramen. The integrity of this line essentially excludes a glomus jugulotympanicum tumor. **D**, Coronal image shows demineralization of the margins (*arrowheads*) as well as the soft tissue of the intratympanic portion of the tumor (*arrow*). (Courtesy of Dr. H.D. Curtin.)

the jugular tubercle, the hypoglossal canal, and portions of the foramen magnum and the clivus. Anterosuperior extension of tumor may involve the cavernous sinus (Fig. 25-77).

Angiographic Features

Paragangliomas are characteristically hypervascular (Figs. 25-69 and 25-70).[299, 300] There are enlarged feeding arteries and rapidly draining veins, and the tumor blush is coarser than in meningiomas but less so than in AVMs. The blush is not as prolonged as in meningiomas. The most common feeders are branches of the ascending pharyngeal artery, which supplies the inferomedial compartment of the tumor around the jugular foramen and the medial tympanic cavity (Figs. 25-70 and 25-71).[262] Other common feeders are the posterior auricular, stylomastoid, and occipital arteries, which supply the posterolateral compartment in the

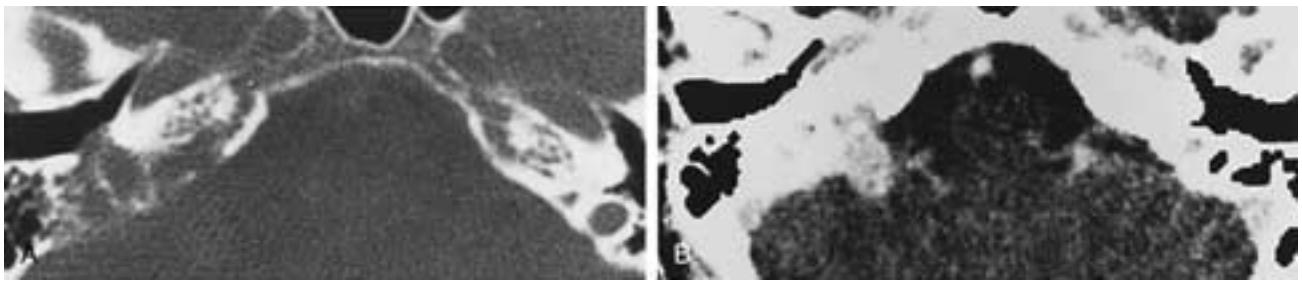
mastoid region. Larger tumors derive their blood supply anteriorly from the internal maxillary (anterior tympanic branch) and superiorly from the internal carotid (carotico-tympanic and lateral clival branches).[299, 300] Even larger tumors receive an additional blood supply from the contralateral carotid artery or the vertebral artery from its meningeal and even pial branches. A pial arterial supply signifies transdural involvement.[301] The angiographic vascularity is sufficiently characteristic that some authors believe it is diagnostic and that biopsy is not necessary.[283] Exceptions that should be considered include metastatic pheochromocytoma, metastatic hypernephroma, metastatic thyroid carcinoma, and hemangiopericytoma.[302] Retrograde jugular venography is now seldom indicated because intravenous tumor extension in itself does not determine the surgical approach (Fig. 25-76).

MR Imaging Appearance

In paragangliomas larger than 2 cm, an apparently unique salt-and-pepper pattern of hyperintensity and hypointensity on T1-weighted and T2-weighted images has been described (Figs. 25-71 and 25-72).[303] Also identified are the serpentine and arborizing flow voids of the hypertrophic medium-sized and larger tumor vessels (Fig. 25-73). These findings, reflecting hypervascularity, are highly suggestive of paragangliomas. The signal intensities from the tumor should be carefully distinguished from those of bone marrow and from mastoid secretions accumulated by virtue of tumor obstruction of the tympanic cavity or eustachian tube (Fig. 25-73). High intensity from stagnant blood in the jugular bulb must not be mistaken for a jugular foramen tumor (Fig. 25-75).

The tumor signal intensity is generally more than that of cortical bone, aerated air cells, and flowing blood but less than that of bone marrow. A dropout effect in the early enhancement pattern of paraganglioma may distinguish this lesion from other tumors.[291] Demonstration of this phenomenon requires ''dynamic'' MR scanning and takes advantage of the fact that if the concentration of gadolinium is sufficiently high, there is actually a signal decrease. Multiple images are taken at the same level as the gadolinium is administered and passes through the tumor. The signal coming from the tumor first rises as the bolus reaches the tumor. However, because of the large volume of blood within the tumor, the gadolinium transiently reaches a high enough concentration that there is actually a signal drop. As the gadolinium concentration of the initial bolus is diluted, the signal increases once again. Tumor types other than paraganglioma do not show this phenomenon.[291]



VIEW IMAGE

FIGURE 25-70 Glomus jugulare tumor. Selective external carotid angiogram. The characteristically hypervascular tumor is supplied by the hypertrophic ascending pharyngeal artery (*arrow*). Note the early draining vein (*arrowhead*) seen during the midarterial phase. The differential diagnosis includes other hypervascular tumors such as metastatic hypernephroma, metastatic pheochromocytomas, myeloma, and so on (see Fig. 25-122).

Although MR imaging does not show the bone changes or the tumor relationships to the bony landmarks as well as high-resolution CT, it defines the infralabyrinthine soft tissue extension better than CT (Fig. 25-72). Thus the two procedures are sometimes of complementary value (Fig. 25-74).

MRA has not reliably demonstrated the characteristic tumor vascularity invariably seen on catheter angiography, and postcontrast enhancement in the jugular vein may be difficult to differentiate paraganglioma from a true jugular tumor. Vogl et al. found MR venography helpful in such cases (Fig. 25-74E,F).[290]

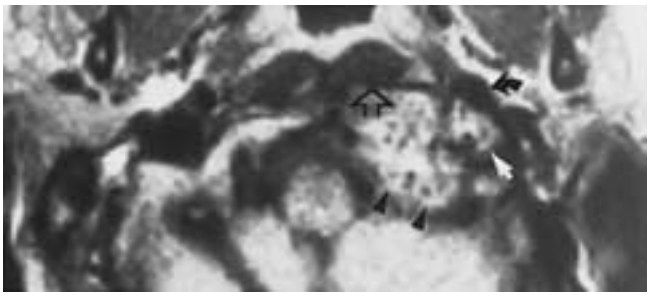
After radiation therapy, stabilization or reduction in tumor size, decreased enhancement, diminished flow voids, and reduced T2-weighted signal intensity indicate local control.[304] Bone demineralization and erosion, however, may persist. Rarely does the actual tumor mass resolve completely after irradiation.

Radionuclide Scintigraphy

Indium-111-octreotide, recently made available commercially, shows greater sensitivity than iodine-123-metaiodobenzyl-guanidine (MIBG) to paragangliomas and appears useful in detecting multicentric, metastatic, or recurrent tumors.[305–307]

Treatment and Surgical Classification

Paragangliomas can be lethal if left untreated.[283] Current treatment includes mainly resection for cure or radiation for long-term control.[308–311] Using the infratemporal fossa approach advanced by Fisch, the entire petrous bone can be resected, including a portion of the clivus.[307, 308, 312]



VIEW IMAGE

FIGURE 25-71 Glomus jugulare tumor. Proton density image. Heterogeneous hyper- and hypointensity are characteristically seen in larger paragangliomas. This tumor has only a small component in the jugular fossa (*arrow*) posterior to the carotid (*curved arrow*) but has a large component in the infralabyrinthine skull base (*arrowheads*) displacing the longus colli muscle anteriorly (*open arrow*).

VIEW IMAGE

FIGURE 25-72 Glomus jugulare tumor. **A** and **B**, T1-weighted pre- and postgadolinium images. The heterogeneously hypointense tumor is located in the jugular fossa, extending into the parapharyngeal space and foramen magnum, with temporal bone and clivus invasion. Areas of signal void within the tumor are related to hypertrophic neoplastic vessels. The tumor shows strong enhancement after gadolinium administration.

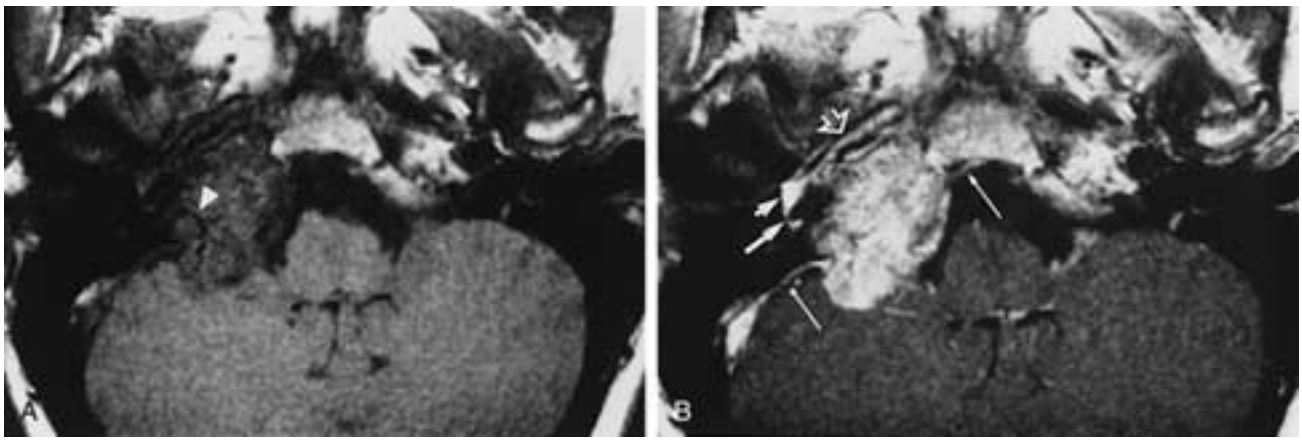
Elaborate classifications have been devised matching tumor extent to surgical procedure (Tables 25-4 and 25-5).[309, 313] The details are pertinent only to those frequently involved in such cases, but the principles behind the classifications are of practical importance to those consulted even only occasionally.

1. A tumor that is intratympanic, intramastoid, or both is resectable by a transmeatal or transmastoid approach, which can be performed by most otologists (Fig. 25-64).
2. A tumor that involves the jugular bulb requires expertise in neck surgery in addition to mastoid surgery.
3. A tumor involving the carotid canal or the infralabyrinthine compartment requires the infratemporal fossa approach used only at neurotologic or skull base centers (Fig. 25-67).
4. A tumor with a transdural component calls for neurosurgical in addition to neurotologic expertise (Fig. 25-68).
5. Cavernous sinus or massive foramen magnum tumors may be unresectable (Fig. 25-77). Modern imaging techniques are thus indispensable in helping to decide the necessity of referral and the choice of proper management.

In tympanicum tumors the surgical blood loss is small, and preoperative embolization is not indicated.[314] In jugulare tumors, the blood loss is at least 1 or 1.5 L and often much more.[314, 315] Preoperative embolization reduces the blood loss by 1 L or more and is now commonly performed.[300, 301, 314–317]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of paragangliomas and the appropriate imaging choices depend on the clinical presentation, which may be either (1) a retrotympanic or intratympanic mass with or without pulsatile tinnitus or (2) deficits of



VIEW IMAGE

the caudal cranial nerves. When the clinical presentation is a retrotympanic or intratympanic mass, high-resolution CT is the modality of choice for the initial imaging modality. MR imaging may follow, if necessary. When a patient presents with deficits of the caudal cranial nerves, MR imaging is the imaging modality of choice. CT may be used as a supplement.

Retrotympanic or Intratympanic Masses

For a list of intratympanic masses, see Box 25-2.

Pulsatile Masses

Although paraganglioma is the most common cause of a pulsatile mass with conductive hearing loss, the otologist is confronted with the following important differential considerations in such a clinical setting: (1) glomus tympanicum tumor confined to the middle ear, (2) glomus jugulare tumor involving the jugular bulb, (3) aberrant carotid artery, and (4) exposed jugular bulb.[318, 319]

An experienced otologist can usually, but not always, distinguish these conditions by their appearance (Table 25-6). Ill-advised biopsies performed on aberrant carotid arteries or exposed jugular bulbs have resulted in massive hemorrhage or hemiplegia.[320, 321] To prevent inappropriate intervention, the radiologist must identify the characteristic findings of the aberrant carotid artery or the exposed jugular bulb on CT[319, 322] (see Chapter 26). MRA may serve to confirm the diagnosis. Angiography usually is not necessary.[319] CT also distinguishes glomus tympanicum tumor, which requires no angiography and limited surgery, from glomus jugulare tumor, which requires angiography, preoperative embolization, and extensive surgery (Figs. 25-64 to 25-69).[294, 319]

Two rarer arterial anomalies may clinically resemble the aberrant carotid artery. Both lesions are associated with dehiscence of the carotid plate: the laterally displaced internal carotid artery herniating into the middle ear and an aneurysm of the internal carotid artery from the junction between its vertical and horizontal intrapetrous segments located in the middle ear.[323–325] MRA may be used to confirm the diagnosis. The persistent stapedial artery may

Table 25-4
GLASSCOCK-JACKSON CLASSIFICATION OF PARAGANGLIOMAS

Tumor Type	Anatomic Extent	Surgical Procedure
Glomus Tympancium		
I	Small mass limited to promontory	Transcanal
II	Completely filling middle ear space	Extended facial recess
III	Filling middle ear and extending into mastoid	Extended facial recess
IV	Filling middle ear, extending into mastoid or through tympanic membrane to fill external auditory canal; may extend anterior to carotid	Extended facial recess
Glomus Jugulare		
I	Small; involving jugular bulb, middle ear, and mastoid	Traditional skull base dissection
II	Extending under internal auditory canal, may have intracranial extension	Traditional skull base dissection
III	Extending into petrous apex; may have intracranial extension	Modified infratemporal fossa approach
IV	Extending beyond petrous apex into clivus or infratemporal fossa; may have intracranial extension	Modified intratemporal fossa approach

or may not be visible on otoscopy, but it can be seen enlarging the anterior portion of the tympanic facial nerve canal on CT.[326]

Other Benign Lesions

Other intratympanic masses may be encountered from time to time and may be indistinguishable from glomus tympanicum tumors on CT, especially when they fill the tympanic cavity and obscure their precise origin. However, all of these lesions are rare and benign. The surgical approach for them is similar as long as the lesions are confined to the middle ear.[295] These lesions are discussed later along with malignant tumors of the middle ear.

Jugular Foramen Masses

For a description of jugular foramen masses, see Table 25-7. About 10% of the tumors involving the jugular foramen are not paragangliomas. These lesions include schwannoma of the caudal cranial nerves, meningioma, carcinomas (primary and metastatic), chondrosarcoma, and extension from nasopharyngeal carcinoma.

Jugular Foramen Schwannomas

Schwannomas of the caudal cranial nerves are rare.[20, 21] Jugular schwannomas, which include schwannomas from the glossopharyngeal, vagus, and spinal accessory nerves, are not always distinguishable from one another (Figs. 25-33 and 25-34). They have been classified into three types according to their location: (1) type A tumors grow predominantly intracranially, (2) type B tumors grow predominantly at the jugular foramen, and (3) type C tumors grow predominantly extracranially.[201] Type A tumors (Fig. 25-33) tend to cause acoustic or cerebellar symptoms, and type B and C tumors (Fig. 25-34) tend to be associated with the jugular foramen syndrome.[201, 202]

Schwannomas expand the jugular foramen symmetrically in contrast to paragangliomas, which often extend along dural sinuses and fissures and infiltrate the bone (Figs. 25-33 and 25-34).[20, 202, 298] Their angiographic hypervascularity is much less than that of paragangliomas, and small

Table 25-5
FISCH CLASSIFICATION OF PARAGANGLIOMAS

Tumor Type	Anatomic Extent	Surgical Procedure
A	Localized to middle ear cleft	Transmeatal
B	Limited to tympanomastoid area, with no infralabyrinthine compartment involvement	Combined transmeatal and transmastoid approach
C	Involving infralabyrinthine compartment and extending into petrous apex	Infratemporal fossa approach
C_1	Destroying jugular foramen and bulb, with limited involvement of vertical carotid canal	Usually sacrificing CN IX
C_2	Destroying infralabyrinthine compartment and invading vertical carotid canal	Usually sacrificing CN IX and X
C_3	Involving infralabyrinthine and apical compartments, with invasion of horizontal carotid canal	Usually sacrificing CN IX, X, and XI
D	With intradural extension	
D_1	Intradural extension less than 2 cm in diameter	Infratemporal fossa approach
D_2	Intradural extension greater than 2 cm in diameter	Two-stage neurosurgical-otologic removal
D_3	Inoperable intradural invasion

scattered ''puddles'' of contrast medium are seen in the midarterial, capillary, and venous phases, with no arteriovenous shunting.[201, 203, 327, 328]

The CT and MR imaging appearances of jugular schwannomas are similar to those of acoustic schwannomas, varying with the proportion of cellular and cystic components of the tumor. The tumor itself, especially its extracranial component along the carotid sheath, is best demonstrated on MR imaging, and coronal and sagittal imaging has been another advantage of MR imaging over CT (Fig. 25-34). More recently, multidetector CT has produced excellent multiplanar images as well. CT with bone detail best demonstrates the foraminal changes and is most helpful in differentiating schwannomas from paragangliomas and jugular from hypoglossal schwannomas. Glossopharyngeal schwannomas can be suggested when there is selective enlargement of the pars nervosa. Vagus and spinal accessory schwannomas tend to arise slightly more laterally at the junction of the pars nervosa and vascularis.

Table 25-6
OTOSCOPIC DIFFERENTIAL DIAGNOSIS OF PULSATILE INTRATYMPANIC MASSES

Aberrant carotid artery	Pink	Anteroinferior quadrant
Exposed jugular bulb	Blue	Posteroinferior quadrant
Glomus tympanicum tumor	Reddish purple	Posteroinferior quadrant
Glomus jugulare tumor	Reddish purple	Posteroinferior quadrant

Hypoglossal Schwannomas

Much of what has been said about jugular foramen schwannomas also applies to hypoglossal schwannomas. These tumors may be intracranial or extracranial or may be dumbbell-shaped, extending into both spaces (Fig. 25-78). In addition, because of the proximity of the hypoglossal canal to the foramen magnum, caudal intraspinal extension has been observed.[20]

Besides ipsilateral hemiatrophy of the tongue, other caudal cranial nerve deficits may develop as the tumor enlarges, and medullary and cerebellar compression and hydrocephalus may follow.[329, 330] In fact, many patients with intracranial hypoglossal schwannomas initially present with cerebellar symptoms or hydrocephalus rather than tongue dysfunction.[330]

Well-defined erosion of the hypoglossal canal is characteristic, although not invariably present.[331] After eroding the hypoglossal canal, the tumor may also erode the jugular foramen, the jugular tubercle, and the clivus, making differentiation from schwannomas of the jugular foramen difficult.[329]

Meningiomas

In addition to their common site of origin on the posterior petrous surface, meningiomas may rarely arise from within the temporal bone. Nager et al. list four such sites: (1) the internal acoustic meatus, (2) the jugular foramen, (3) the region of the geniculate ganglion, and (4) the sulcus of the greater and lesser superficial petrosal nerves.[332] Jugular foramen meningiomas show some of the behavior patterns

Table 25-7
DIFFERENTIAL DIAGNOSIS OF JUGULAR FORAMEN TUMORS

Tumor	CT Margin	Angiographic Vascularity	Typical MR Imaging Appearance
Schwannoma	Well-defined	Minimal to moderate	Homogeneous or cystic
Paraganglioma	Ill-defined	Marked	Salt-and-pepper
Meningioma	Subtly ill-defined	Minimal	Homogeneous
Malignant tumors (carcinomas, metastases)	Ill-defined	Minimal to marked	Homogeneous
Chondrosarcoma	Ill-defined	Minimal	Inhomogeneous T2
Nasopharyngeal carcinoma	Medial	Minimal	Infiltrative

VIEW IMAGE

FIGURE 25-78 Trilobed hypoglossal schwannoma. **A** and **B**, T1-weighted images. The tumor is difficult to distinguish from jugular foramen schwannoma on transverse images, but its more caudal position at the medullocord junction is quite apparent on the coronal image (**B**). (Compare with Fig. 25-33D). The intracranial component of the tumor deforms the medulla (*arrowheads*), and the parapharyngeal component displaces the jugular vein (*curved arrows*).

of paragangliomas. Locally invasive around the jugular foramen, they grow through the jugular plate into the hypotympanum, descend through and along the jugular vein, and may show a small extension into the posterior fossa (Fig. 25-79).[333, 334]

On CT, their soft tissue components are indistinguishable from those of paragangliomas. Their bone margins, however, are better defined than those of paragangliomas but less well defined than those of schwannomas (Fig. 25-79F). Subtle sclerosis may be present in the infiltrated bone.

On MR imaging, they appear as other meningiomas do and lack the salt-and-pepper pattern of paragangliomas (Fig. 25-79A,B).[129, 135, 136, 303] On angiography, they show minimal vascularity, less than that of schwannomas, and do not have the prolonged cloudlike blush commonly seen in supratentorial meningiomas.

Malignant Tumors

Carcinoma, sarcoma, myeloma, metastasis, and other malignancies may be indistinguishable from paragangliomas on CT if they happen to destroy the jugular fossa (Figs. 25-80 to 25-82).[335] They usually lack the salt-and-pepper appearance of paragangliomas on MR imaging.[303] On angiography, most of them are much less vascular than paragangliomas. Exceptions to be considered include metastatic hypernephroma, metastatic pheochromocytoma, metastatic thyroid carcinoma, and hemangiopericytoma.[302, 336]

Chondrosarcomas

Occurring along the petrooccipital fissure, chondrosarcomas may involve the jugular foramen from its medial aspect and may contain calcifications (Figs. 25-83 and 25-84).[337]

Nasopharyngeal Carcinoma

Direct extension from nasopharyngeal carcinoma also may involve the jugular foramen, usually involving the medial aspect along with the petrooccipital fissure (Fig. 25-85).

Miscellaneous

An amyloidoma has been reported in the CPA and the jugular foramen, appearing as a patchy hyperdense mass with slight contrast enhancement and angiographic avascularity.[338] Skull base osteomyelitis can involve the jugular foramen as well as the rest of the temporal bone (Fig. 25-86). The clinical presentation helps differentiate osteomyelitis from tumors but the imaging appearances can overlap.

TUMORS INVOLVING THE FACIAL NERVE

Of the 1575 cases of facial nerve disorders managed over a 20-year period by May, only 91, or 6%, were caused by tumors; 895, or 57%, were caused by idiopathic or Bell's palsy, which classically begins abruptly and resolves or at least improves spontaneously within a few weeks.[287, 339] Thus the majority of facial nerve palsies do not require a radiologic workup.

The other causes of facial nerve disease in May's series were herpes zoster oticus (7%), trauma (17%), infection (4%), congenital (3%), hemifacial spasm (2%), central nervous system disease (1%), other (2%), and unknown (1%). However, May pointed out that 46 of the 91 tumors in his series were initially misdiagnosed as Bell's palsy.[339] Hence slow progression of paralysis beyond 3 weeks, absence of recovery after 6 months, ipsilateral recurrence, and other signs such as hemifacial spasm atypical of Bell's palsy demand a thorough radiologic investigation for

tumor.[339] Abrupt onset alone is no assurance that the palsy is not caused by tumor.[340, 341]

Manifestations of Facial Nerve Dysfunction and Lesion Localization

The facial nerve, in its long course from the pons through the CPA, IAC, and facial nerve canal (FNC) to its arborization in the parotid gland, is subject to involvement by tumors of many types at different locations, and unfocused or misdirected imaging studies have often delayed diagnosis.[310, 311] Awareness of clinical localization is of great assistance to the radiologic investigation.

Facial nerve paralysis is classically divided into central and peripheral categories. Central lesions are located above the motor nucleus in the brainstem and result in contralateral motor weakness of the lower part of the face. Peripheral nerve lesions cause ipsilateral motor weakness of both the upper and lower parts of the face. Hemifacial spasm is an irritative phenomenon of the facial nerve. Myokymia is a fine fibrillary activity of all muscles on one side of the face and is most often seen in patients with multiple sclerosis or brainstem glioma.[287]

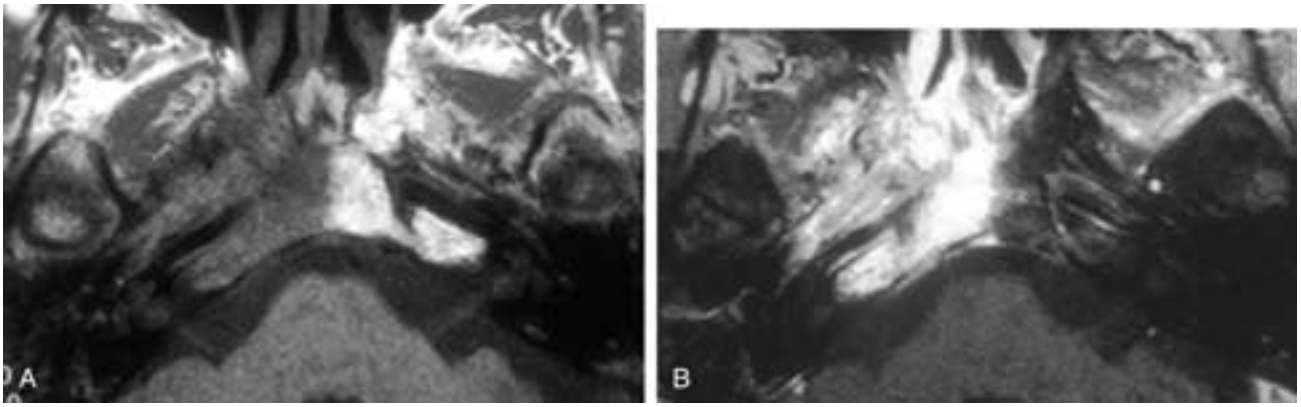
Facial nerve compromise in the brainstem is likely to be accompanied by palsy of other cranial nerves and perhaps contralateral long tract signs. In the CPA and the IAC, it is likely to be accompanied or preceded by symptoms involving the acoustic nerve.[342, 343]

A facial nerve lesion within the temporal bone can be further localized according to the presence or absence of involvement of (1) the greater superficial petrosal nerve (lacrimation), (2) the nerve of the stapedius muscle (stapes reflex), and (3) the chorda tympani nerve (taste and salivation). Thus a lesion may be described as suprageniculate if all three are affected, suprastapedial if (2) and (3) are affected, infrastapedial if only (3) is affected, and infrachordal if all three are intact.[344] However, in the case of tumors, the accuracy of ''topognosis'' has been questioned because tumors may spare some of the fibers in the involved segment of the nerve. Thus, for instance, a tumor of the geniculate ganglion may leave the stapedial reflex intact. However, a positive finding is considered accurate. If, for instance, lacrimation is affected, then the lesion must be at the geniculate or more central.

If the origin of a peripheral facial palsy is clinically unlocalized or is localized to the pons, the CPA, or the IAC, MR imaging including the pons and the parotid gland is the preferred imaging modality. If a lesion is clinically localized to the FNC, MR imaging and high-resolution CT with maximum bone detail may both be used. For acute facial palsy, Gd-MR imaging is clearly the modality of choice.[345, 346]

It should be noted that tumor destruction of the FNC does not necessarily cause facial nerve palsy if there is no invasion of the facial nerve.[347] Conversely, perineural and intraneural tumor spread (notably from adenoid cystic carcinoma of the parotid gland) can extend along a considerable length of the facial nerve within the FNC, causing facial palsy but little if any bone change (Fig. 25-87).[347, 348] In such a case, Gd-MR imaging may show the abnormality more readily than CT (Fig. 25-88).

There are other important caveats when imaging facial



VIEW IMAGE

nerve palsy. On Gd-MR imaging, mild to moderate enhancement of the facial nerve, because of the presence of the perineural venous plexus, is seen in the facial nerve canal in the majority of normal subjects.[349] Such physiologic enhancement is usually symmetric in intensity. Thus, in a patient with unilateral symptoms, it is only when there is asymmetric facial nerve enhancement or apparent enlargement of the nerve that pathology should be suspected. Intense enhancement along the nerve, with or without discernible swelling, is found in idiopathic Bell's palsy and herpes zoster oticus (Ramsay-Hunt syndrome).[345, 350–353] In these inflammations the neural enhancement occurs not only along the facial nerve canal, including the labyrinthine segments, but also in the fundus of the IAC. These

enhancements should not be mistaken for tumors. Also not to be confused with a facial nerve tumor is enlargement of the tympanic facial nerve canal by a persistent stapedial artery, best seen on CT (Chapter 26) and enlargement of the geniculate fossa by an arachnoid diverticulum.[354]

Tumors

Tables 25-8 and 25-9 show the gamut of benign and malignant tumors, respectively, in May's experience of 91 tumors causing facial palsy.[339] In Fisch and Rüttner's series of 43 intratemporal tumors involving the facial nerve, there were 12 congenital cholesteatomas (10 supralabyrinthine and 2 apex), 9 schwannomas (neuromas), and 9 hemangiomas (4 cavernous and 5 ossifying). Less common benign tumors included three meningiomas, three glomus jugular tumors, and one arachnoid cyst.[341, 355] Malignant tumors included four squamous carcinomas and two rhabdomyosarcomas. Although the majority of Fisch and Rüttner's patients had slowly progressive facial palsy, six had facial palsy of sudden onset. This group included three of the five patients with ossifying hemangiomas.[341]

Facial nerve tumors in the CPA and IAC share the same differential diagnosis as acoustic schwannomas, and those in the tympanic cavity share the same differential diagnosis as intratympanic paragangliomas. These differential diagnoses have been discussed in the sections on Acoustic Schwannomas (Neuromas) and Paragangliomas and Jugular Foramen Tumors, respectively. The three most common tumors in Fisch and Rüttner's series—schwannoma, hemangioma, and congenital cholesteatoma—are described in detail in the following three sections. All three tend to occur in the region of the geniculate ganglion (Table 25-10).[341]

Facial Schwannomas

Facial schwannomas can occur along any segment of the nerve (Figs. 25-31 and 25-32, 25-89 to 25-97).[356] The

geniculate ganglion is frequently involved and is often affected whether the tumor extends primarily proximally or distally.[199]

The clinical presentations of facial schwannomas depend on the segment of the nerve involved.[262] Interestingly, fewer than half of the facial schwannomas initially appear with facial palsy.[198, 199] Many have no facial nerve symptoms at all. In one series, only two of eight cases had facial palsy as a presenting symptom, and only two of the eight had hemifacial spasm.[199] This may result partly from the fact that some schwannomas compress but do not invade the nerve. Consequently, nerve deficits result only where high pressure can be exerted on the nerve. However, even when the tumor exerts enough pressure to enlarge the facial nerve canal, paralysis is not universally present, and some investigators have indicated that a facial paralysis occurs only after a substantial percentage of the nerve fibers have been destroyed.

In general, facial schwannomas in the CPA and the IAC are characterized by sensorineural hearing loss, apparently because the more thinly myelinated sensory fibers of the acoustic nerve are more vulnerable to compression than are the more thickly myelinated motor fibers of the facial nerve (Figs. 25-32 and 25-33).[199] Schwannomas straddling the posterior and middle cranial fossae may cause both acoustic and facial nerve symptoms (Fig. 25-90). Schwannomas in the geniculate region grow silently into the middle cranial fossa, reaching several centimeters in diameter before hearing loss or facial nerve symptoms appear (Fig. 25-91).[357] Those in the tympanic segment tend to first cause conductive hearing loss by ossicular interference (Figs. 25-92 and 25-93). Those in the mastoid segment are likely to have facial palsy as the presenting symptom (Figs. 25-94 and 25-96).[199] Finally, those tumors distal to the stylomastoid foramen appear as painless neck masses.[358] Multisegment tumors (Figs. 25-94 and 25-95) are usually accompanied by facial nerve symptoms.[359]

Excision of a facial schwannoma almost always requires segmental resection of the facial nerve. Tumor removal is usually postponed in patients without facial weakness, but it should be performed before substantial loss of neural function occurs. In most cases, it is best to resect the tumor and restore continuity of the nerve with an end-to-end anastomosis or a ''cable'' nerve graft.[360]

Facial schwannomas are often sausage-shaped, expanding long segments of the FNC (Figs. 25-89, 25-94 and 25-95). There may be more than one ''link,'' for example, a component in the IAC and a component in the middle cranial fossa connected via a narrow waist through the labyrinthine FNC (Figs. 25-90 and 25-97). Their CT density and enhancement and MR imaging intensity are similar to those of acoustic schwannomas.

When facial schwannomas occur in the CPA or in the IAC, they may be clinically and radiologically indistinguishable from acoustic schwannomas (Figs. 25-31 to 25-33).[200, 361] Eccentricity of tumor mass to the axis of the IAC may be a diagnostic clue.[362] The differential diagnoses in these two regions are identical to those of acoustic schwannomas (Tables 25-2 and 25-4).

For differential diagnosis in the geniculate ganglion

region, other tumors prevalent in that location, namely, epidermoid cyst, hemangioma, and meningioma, are the primary considerations (Figs. 25-98 to 25-100). The changes seen on high-resolution CT are helpful: the borders of hemangiomas are not sharp (Figs. 25-98 and 25-99), those of epidermoids are extremely sharp (Fig. 25-101), and those of schwannomas are moderately sharp (Figs. 25-90 to 25-96). Hemangiomas and epidermoids are usually small, and schwannomas are variable in size and may be quite large (Figs. 25-90, 25-91, 25-94, 25-98 and 25-100). Hemangiomas may contain intratumoral bone (ossifying hemangioma) (Figs. 25-42, 25-43, 25-98 and 25-99).[241, 242] Epidermoids are isodense or hypodense and are nonenhancing.[363] The CT and MR imaging features of meningioma at this location may be expected to resemble those in the CPA.

Facial schwannomas straddling the posterior and middle fossae transgress the petrous bone through its midsection

Intratemporal vascular tumors: detection with CT and MR. Radiology 1989;171:443–448.)

(Fig. 25-90), in contrast to trigeminal schwannomas, which are located at the petrous apex (Fig. 25-28).[364]

Geniculate region schwannomas, when sufficiently large, may be mistaken for temporal lobe gliomas or metastases (Fig. 25-91).[357, 365] Coronal images are helpful in the evaluation of tumors in this region, and smooth enlargement of the facial nerve canal should be a distinguishing feature in favor of a facial schwannoma. Multisegment facial schwannomas may need to be differentiated from perineural spread of malignant tumor (Fig. 25-87).

Enlargement of the proximal tympanic segment of the FNC by a persistent stapedial artery must not be mistaken for a facial nerve schwannoma.[326] In addition, developmental dehiscence of the FNC, present in about half of the temporal bones, most often near the oval window, should not be mistaken for an area of localized destruction.[366]

Gd-MR imaging rivals CT with bone algorithm in the early detection of intratemporal facial nerve tumors (Figs. 25-31, 25-91 and 25-92).[367] However, for precise correlation with bony landmarks, CT with bone detail remains invaluable (Figs. 25-90 to 25-94).

Benign Vascular Tumors

Hemangiomas or vascular malformations along the intratemporal course of the facial nerve were once thought to be rare.[368, 369] More recently, however, they have been found in some series at least as often as the much better-known schwannomas.[241, 341, 370] Hemangiomas are composed of thin-walled vascular spaces. Vascular malformations are composed of thick-walled vascular spaces lined by a single layer of endothelium surrounded by fibroblasts and collagen. The latter histologic type is the more common of the two. Because the two histologic variations may coexist in a single mass, they have been grouped together under intratemporal benign vascular tumors (IBVT), and the terms are sometimes loosely interchanged.[241, 371]

Hemangiomas may be further categorized into cavernous and capillary types by the predominant size of their vascular spaces. Vascular tumors often grow among bone trabeculae and may form bone (Figs. 25-42, 25-43, 25-98 and 25-99). In the latter case they have been called ossifying hemangiomas.[341, 370] All of these tumors are benign.[241]

IBVT cause nerve deficits by invasion rather than compression. Therefore, unlike schwannomas, they cause hemifacial spasm and facial palsy early; and if located in the IAC, they also cause sensorineural hearing loss to a greater degree than would be expected based solely on their size (Figs. 25-42 and 25-44).[241, 264, 272, 372] Although facial nerve resection and grafting may be necessary in many cases, in contrast with schwannomas, IBVT, being of extraneural origin, if operated on early, can at times be removed, with preservation of facial nerve continuity. Early detection is therefore extremely important.

Early detection of IBVT requires excellent imaging techniques and meticulous scrutiny. Although many of these tumors are missed initially because of inadequate technique, some are missed even with excellent technique because of their small size and subtle findings.[241, 242, 370]

IBVT occur most often at the geniculate ganglion region, next most often in the IAC, and least often at the posterior genu. They are usually less than 1 cm in diameter.

These lesions may contain intratumoral bone spicules, best seen on CT (Figs. 25-42, 25-43 and 25-99).[241] In the labryinthine FNC and at the geniculate ganglion, they show subtle findings that may include irregular and indistinct bone margins and reticular or ''honeycomb'' bone (Figs. 25-43 and 25-98).[241, 370] At the posterior genu they are focal, in contrast to schwannomas, which tend to be segmental (Fig. 25-93). Although the IBVT enhances with contrast, enhancement does not play a significant role in detection because such density changes in a small intratemporal lesion, contiguous to bone, are difficult to discern.

On MR imaging, vascular tumors are extremely well demonstrated when located in the IAC (Fig. 25-44).[242] They are isointense to mildly hyperintense on T1-weighted images and are markedly hyperintense on T2-weighted images, more so than the typical schwannoma. When located in the geniculate ganglion region, they are less reliably demonstrated by MR imaging without gadolinium than by CT with bone detail. When they are identifiable on MR imaging, they show nonhomogeneous signal intensities, which may be the MR imaging correlate of the CT ''honeycomb'' bone (Fig. 25-98). Thin sections, high matrices, close slice spacing, and the use of gadolinium may improve the MR imaging results.

Epidermoid Cysts

Besides arising intradurally from the CPA, epidermoid cysts, also called congenital or primary cholesteatomas, may arise extradurally from the petrous apex, the supralabyrinthine temporal bone, or the tympanic cavity. From the petrous apex they attain considerable size before involving the facial and acoustic nerves in the CPA or the IAC, and thus clinically they appear late (Fig. 25-101). From the supralabyrinthine region they readily erode the proximal FNC and tend to be discovered early, while still small (Fig. 25-100). Of the epidermoids causing

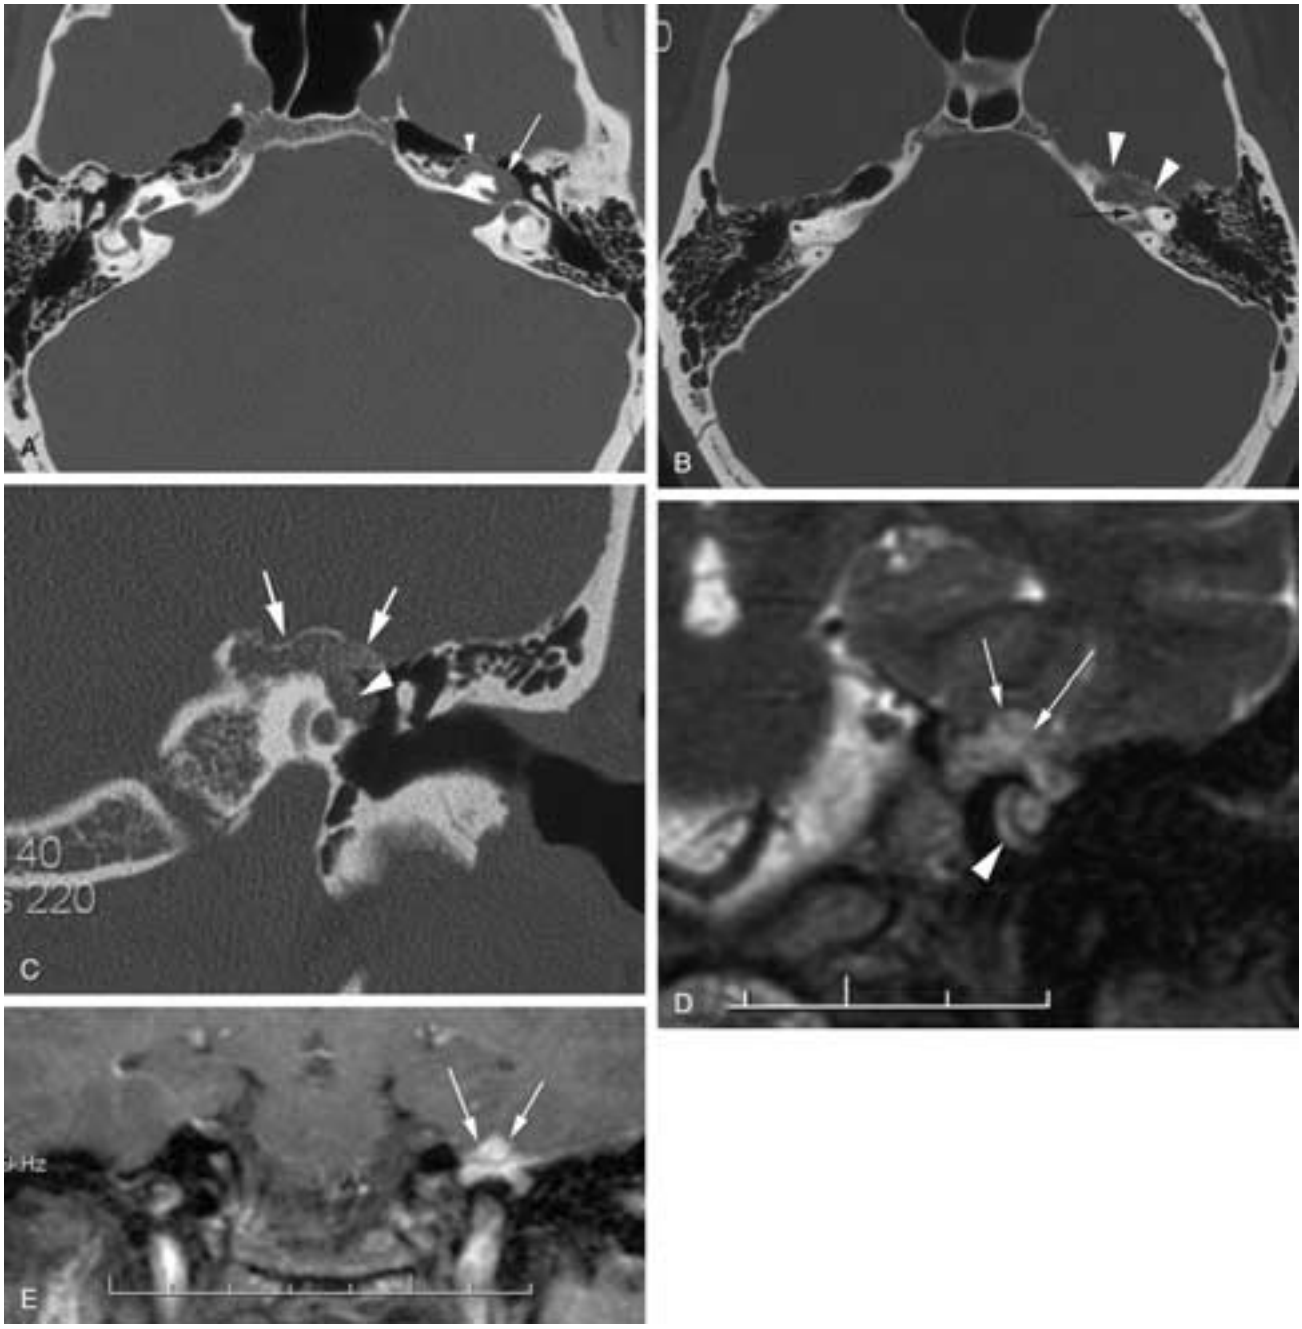

FIGURE 25-99 Intratemporal vascular tumor in the region of the geniculate ganglion. **A**, Axial CT image through the geniculate ganglion shows expansion of the facial nerve (*arrow*). There is irregular bone extending medially toward the petrous apex (*arrowhead*). **B**, Slightly superior to **A**, there is demineralization in the region of the labyrinthine segment of the canal (*black arrow*). Note that the lesion (*arrowheads*) contains small spicules of bone. **C**, Coronal CT image shows the demineralized bone (*arrows*). The abnormality extends inferiorly to enlarge the FNC (*arrowhead*) and involve the facial nerve. **D**, Coronal T2-weighted MR image shows the relatively high signal (*arrows*) of the vascular lesion. FIGURE 25-102 Acquired epidermoid of the temporal bone, right ear. **A**, Axial CT shows a sharply and smoothly marginated lobular mass extending from the middle ear cavity, anterior to the cochlea to expand the petrous apex, eroding portions of the cochlear capsule. **B**, Axial CT with a soft-tissue algorithm shows the mass to be mildly hypodense relative to brain. The patient's facial weakness was due to erosion in the geniculate ganglion region (*arrow*). **C**, Axial T1-weighted MR image shows that the mass is mildly hypointense, with a thin, isointense capsule (*arrowheads*). **D**, Coronal T1-weighted MR postcontrast image. The cholesteatomatous material shows no enhancement; there is enhancement of tissue in the middle and surrounding the capsule (*arrowheads*) as a result of reactive inflammation. (From Jackler RK, Brackmann DE, eds. Neurotology. St. Louis: Mosby-Year Book, 1994.)

facial nerve palsy in Fisch and Rüttner's series, 10 of 12 occurred in this region. From this point of origin they often reach around the superior semicircular canal and extend superomedially to the IAC or laterally into the epitympanum (Fig. 25-100).[363] They may erode the superior surface of the cochlear capsule or the ampullary limb of the superior semicircular canal to the point of fistulization (Fig. 25-100).[341]

On CT their bone margins are characteristically extremely sharp.[341, 363] Their general configuration may be either unilocular or multilocular. Hypodensity compared with brain may or may not be seen.[363] On MR imaging they are hypointense with brain on T1-weighted images but hyperintense on T2-weighted images (Fig. 25-100), and only their capsule enhances.

The petrous apex epidermoid cysts are discussed further in the section on Other Tumors and Cysts of the Temporal Bone. They may involve the facial nerve by expansion toward the IAC. Congenital epidermoid cysts in the tympanic cavity cause conductive hearing loss but rarely cause facial palsy. By comparison, acquired cholesteatomas involve the geniculate ganglion as they grow from the anterior epitympanic space into the petrous apex. (Fig. 25-102).[373]

Miscellaneous Tumors

Two rare lesions may originate along the facial nerve canal. Choristoma, usually consisting of ectopic salivary tissue, arises along the tympanic segment and causes conductive hearing loss. It may be associated with facial nerve and incudostapedial abnormality.[374] Primary paraganglioma, arising in the descending facial nerve canal from paraganglia along the distal Arnold's nerve, should be included in the differential diagnosis of pulsatile tinnitus and facial palsy (Fig. 25-103).[375]

Tumors from adjacent anatomic structures may involve the facial nerve by direct extension, and of these tumors the jugular foramen paraganglioma is perhaps the most common.[288] Papillary cystadenomatous tumor from the endolymphatic sac is rare, but when present it often involves the facial nerve in the medial mastoid bone (Fig. 25-104).[376] Carcinomas of the parotid gland, principally adenoid cystic

and mucoepidermoid, are notorious for perineural extension along the facial nerve, and advanced squamous carcinoma of the external auditory canal may involve the mastoid segment of the facial nerve (Fig. 25-105).[377, 378] On rare occasions, systemic malignancies occurring in the mastoid region may involve the facial nerve. These include embryonal rhabdomyosarcoma in young children, Langerhans cell histiocytosis in children and young adults, lymphoma, and metastases (see the sections on External Auditory Canal and Mastoid).[377, 378]

OTHER TUMORS AND CYSTS OF THE TEMPORAL BONE

Many other tumors and cysts occurring in the temporal bone have not been specifically discussed thus far. These are lesions mainly in the external auditory canal (EAC), the middle ear, the mastoid, and the petrous apex. In the differential diagnosis of an osteolytic lesion of the temporal bone, Chasin and Goodman discussed 25 diseases under eight categories: carcinomas, sarcomas, metastases, benign epithelial lesions, benign nonepithelial lesions, hematologic malignancies, infections and inflammatory lesions, and histiocytosis.[379] Exhaustive as their list was, it was incomplete. For example, one may add mucocele, cholesterol granuloma or cyst (Fig. 25-106), giant cell tumor (Figs. 25-81 and 25-107), intrapetrous carotid aneurysm, xanthoma (Fig. 25-108), and so on.[380–391] The number of possible lesions is indeed enormous (Box 25-3).

On the other hand, the nonspecificity of the bone changes, the CT density, the MR imaging signal intensities, and the degree and pattern of enhancement limit one's ability to provide a specific diagnosis in the vast majority of these lesions. The internal margins of a bone lesion, whether ''geographic,'' ''moth-eaten,'' or ''permeative,'' are reflections of increasing growth rates and not of histologic types.[392] Geographic borders, whether sclerotic-rimmed, well defined, or ill defined, likewise reflect growth rates in ascending order. Rapidly spreading lesions such as osteomyelitis or Ewing's sarcoma may show no visible internal margin. In the temporal bone, the varying degrees of resistance offered by capsular, cortical, diploic, and pneumatized bones may further modify the appearance of the margin of a lesion. Nevertheless, the internal margins do provide a guide to the growth rate of a lesion.

The location of a lesion may alter the differential diagnosis. For example, a destructive lesion with a moth-eaten border around the EAC is probably a squamous carcinoma, but one around the jugular fossa is probably a paraganglioma. The patient's age group also may be helpful in making a diagnosis. For example, carcinoma is more likely in an adult, and embryonal rhabdomyosarcoma is much more probable in a young child. A history of malignancy favors metastasis, and the presence of calcifications suggests meningioma, chordoma, chondrosarcoma, and epidermoid.

Thus the radiologist's principal task is to localize a lesion accurately and to suggest its growth rate rather than to provide a specific diagnosis, at least for those laterally placed lesions that are readily available to inspection and biopsy.[393] In the petrous apex, where a lesion is beyond direct inspection and its surgical access is difficult, the case is different. Besides detection, localization, and characterization, every effort should be made to arrive at a specific preoperative diagnosis. Fortunately, in this location, diagnosis in many cases is possible.

EXTERNAL AUDITORY CANAL

Benign Tumors

Several benign tumor or tumor-like conditions are specific to the EAC. Some of them are not true neoplasms but may be confused with them. Two such soft-tissue lesions are keratosis obturans and EAC cholesteatoma.[394] Keratosis obturans usually occurs in individuals under 40 years of age with a history of sinusitis or bronchiectasis. The condition is usually bilateral, acute, and painful. Keratin plugs occlude the medial portion of the EAC (Fig. 25-109), and the

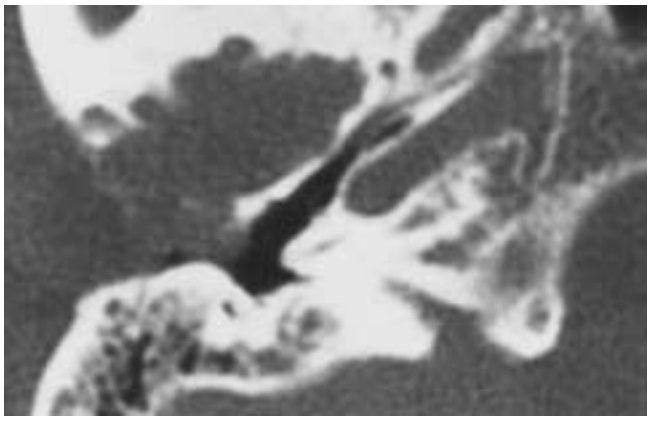
The granulomas have heterogeneous signal intensity with a peripheral hypointense rim due to expanded cortical bone. **C** and **D**, CT bone window images. Cystic, lobulated lesions are seen bilaterally. Granuloma on the right side is more expansile and also has eroded the medial wall of the carotid canal.

adjacent bony canal may be diffusely widened. Reflex hyperemia has been theorized as the mechanism, and treatment consists of removing the plug and treating the granulations.[394]

EAC cholesteatoma occurs in individuals over 40 years of age. Usually unilateral, chronic, and associated with otorrhea, it causes localized erosion of the canal wall and elevation of the epidermis by cholesteatoma embedded in the bony wall (Fig. 25-110). Sequestration of bone and formation of sinus tracts may be present. Circumscribed periostitis is the probable cause. Complete surgical removal of the cholesteatoma sac and the necrotic bone is usually necessary for successful treatment.[394]



VIEW IMAGE

FIGURE 25-107 Benign giant cell tumor. Axial CT. Tumor partially occludes the EAC. Well-defined scalloped borders suggest a benign lesion.

Exostoses of the EAC are sessile multinodular bony masses arising deep in the EAC (Figs. 25-111 and 25-112). They are thought to be caused by prolonged physical, chemical, or thermal irritation—for example, frequent excessive contact with cold sea water for many years. In the case of aquatic exposure, the exostoses are usually asymptomatic until after the tenth year; then pain, infection, and hearing loss may appear. Total canal occlusion is rare.[395, 396]

Osteomas are sporadic, solitary, unilateral, pedunculated growths of mature bone located in the outer portion of the bony EAC (Fig. 25-113). They are much less common than exostoses, and the mastoid is the most prevalent extracanalicular site.[395, 397]

To the clinician, fibrous dysplasia may mimic an osteoma, but differentiation between the two is quite apparent on imaging (Fig. 25-114).[398]

Malignant Tumors

Squamous cell carcinoma is by far the most common malignant tumor of the ear (Figs. 25-82, 25-105 and 25-

Copyright © 2003, Mosby, Inc. All rights reserved.

115).[19, 399] Squamous cell carcinoma may arise in the EAC and spread to the middle ear or arise in the middle ear.[400] Unlike auricular basal cell carcinomas, which are uniformly associated with actinic damage to the epidermis, nearly always are found in men, and are rarely fatal, EAC squamous carcinomas are not associated with such damage, are more common in women, and have a 5-year mortality rate of about 50%.[401] Such carcinoma is frequently preceded by a long history of chronic ear infection. The tumor destroys the adjacent bone in the EAC and middle ear and invades the surrounding soft tissues. Extradural growth into the middle cranial fossa is common, as are mastoid involvement and extension into the soft tissues beneath the temporal bone.[402, 403] The temporomandibular joint, the parotid gland, and the carotid canal can be involved; however, the otic capsule is relatively resistant to erosion.[403, 404] CT accurately predicts tumor extent.[378] Middle ear extension of EAC squamous cell carcinoma reduces the 5-year survival from 56% to 27% (Fig. 25-82).[405] Other predictors of a poor outcome are extensive tumor, facial nerve paralysis, and cervical or periparotid adenopathy.[406] Initial complete resection followed by irradiation is the most effective treatment,[401, 405] except for tumors confined to the EAC without bone involvement, in which case resection alone may suffice.[407] Careful preoperative mapping of the entire tumor must be stressed.

The term *ceruminoma* is used by some authors to include all glandular tumors arising from the apocrine, seromucinous, or salivary glands of the EAC and middle ear.[19] This practice, however, is opposed by other authors who stress the divergent behaviors of the various tumors that are included in this general classification.[408] Adenoid cystic carcinoma is the most common tumor in the group. It is to be distinguished from ceruminous adenoma and pleomorphic adenoma, which are benign lesions, and from ceruminous adenocarcinoma, which has variable malignant potential. Adenoid cystic carcinoma, which histologically and pathologically resembles similar tumors of the salivary gland, is locally invasive and is treated best by radical en bloc resection.[408, 409]

Metastases, basal cell carcinoma, malignant melanoma, chondrosarcoma, osteosarcoma, lymphoma, and myeloma also may occur in the EAC, although much less frequently. Giant cell tumors (Fig. 25-107) and benign chondroblastomas likewise may cause bone destruction.[389, 410, 411] Chronic infections and inflammatory diseases such as malignant external otitis tuberculosis, Wegener's granulo-

	Wegener's granulomatosis
	Acquired cholesteatoma
Histiocytosis	Eosinophilic granuloma
Vascular	Carotid aneurysm

matosis, and histiocytosis (Figs. 25-116 and 25-117) should also be considered.

MIDDLE EAR TUMORS

Benign Tumors

The most common middle ear tumor, paraganglioma (glomus tympanicum tumor), is discussed in detail earlier in the chapter. Other benign middle ear tumors include cholesterol granuloma, hemangioma, facial nerve or chorda tympani schwannoma, congenital cholesteatoma, meningioma, adenomatous tumor of the mixed

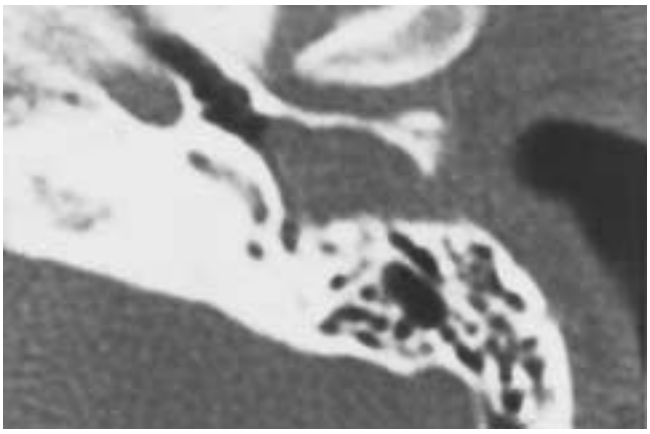

FIGURE 25-109 Keratosis obturans. Axial CT. A soft-tissue plug by itself is not a specific finding. There is mild diffuse thinning of the cortex of the EAC. The tympanic membrane is displaced medially, but the middle ear is normal.

VIEW IMAGE

pattern type (Fig. 25-118), and choristoma (ectopic salivary tissue).

Adenomatous tumor of the mixed pattern type is a benign lesion occurring in the middle ear.[362, 412] Bone invasion is not characteristic, and therefore CT of the lesion gives an appearance that cannot be distinguished from that of chronic ear disease. The only finding at CT may be opacification of the middle ear space. Previously, adenomatous tumors of the middle ear were separated into two subtypes, the mixed pattern and the papillary pattern. The papillary pattern was considered much more aggressive, showing significant bone destruction. Many of these papillary tumors are now considered low-grade malignant adenomatous tumors arising from the endolymphatic sac. These tumors secondarily invaded the middle ear, and this component of the tumor caused the patient to seek medical help, hence the confusion with the less aggressive nonpapillary mixed pattern type. The more aggressive papillary low-grade malignant adenomatous tumors arising from the endolymphatic sac are discussed later in this chapter. Those with the mixed pl
can have variable histology. Most have a glandular

appearance, but sections frequently lose the glandular pattern, and neuroendocrine differentiation suggesting carcinoid tumor has occasionally been identified. The benign mixed pattern lesions do not have a papillary pattern, as do the more aggressive tumors arising in this region.

Most choristomas in the middle ear consist of salivary gland tissue, but neural sebaceous tissue or, rarely, odontogenic remnants also may be found.[413, 414] Salivary choristomas may be accompanied by an incudostapedial or tympanic facial nerve abnormality.[374] A cholesteatoma found behind an intact ear drum without a history of otitis media is considered by some to be congenital in origin.[399, 415] Whether congenital or not, these cholesteatomas account for 2% of all middle ear cholesteatomas.[416] Their most common middle ear sites are the epitympanum and the vicinity of the incudostapedial joint.[415, 417] By comparison, an acquired cholesteatoma is accompanied by evidence of chronic infection.

If discovered early, certain intratympanic tumors may be recognized by their locations. For example, small tympanic paragangliomas can be identified on the promontory (Fig. 25-63); small facial schwannomas (Figs. 25-92 and 25-93), hemangiomas, and choristomas are along the facial nerve canal (FNC); and small chorda tympani schwannomas are on the lateral tympanic wall.[374]

Malignant Tumors

There are several malignant tumors of the middle ear, all of which are rare. Among these lesions, squamous carcinoma is the most common.[400] It is thought to arise secondary to metaplasia of the normal cuboidal or ciliated columnar epithelium.[404] Twenty-three patients treated with mastoidectomy and radiation therapy had a 5-year survival rate of 39%, and death is usually by intracranial extension.[404]

Rhabdomyosarcoma occurs in early childhood.[418] Although rare, embryonal rhabdomyosarcoma is the most common middle ear neoplasm in that age group. Initially the tumor appears as chronic otitis media, and a superficial biopsy often yields only inflammatory granulation tissue. Destruction then rapidly extends beyond the middle ear, and facial nerve palsy is common.[418–420] The MR findings are nonspecific.[421] Although the disease is highly malignant and is usually fatal, multiple-drug chemotherapy and radiation therapy after a mastoidectomy have resulted in several long-term survivals.[419, 422]

Adenocarcinoma and metastases can also occur in the middle ear cleft.[348, 399, 412, 423] In addition, the primary presentation of malignant lymphoma in the middle ear and primary melanoma have been reported.[424, 425]

MASTOID

Tumors of the mastoid are often malignant. These include squamous cell carcinomas, adenocarcinomas, undifferentiated carcinomas (Fig. 25-119), myeloma, lymphoma, and metastases in adults, embryonal rhabdomyosarcoma in young children, and Langerhans cell histiocytosis in children, adolescents, and young adults (Figs. 25-116 and 25-117). Malignant tumors of the mastoid are often large and also may involve the EAC or the middle ear.[400] Their imaging findings are usually nonspecific, and their diagnoses are established by biopsy.

Benign processes principally include osteoma, fibrous dysplasia (Fig. 25-114), descending facial nerve schwannoma, and primary facial nerve canal paraganglioma (Fig. 25-103). Because of its clearer delineation of the bone margins, CT may be more helpful than MR imaging in distinguishing benign from malignant tumors. Contrast, for example, the well-defined sclerotic margins of a large mastoid segment facial nerve schwannoma (Fig. 25-96D) with the infiltrated, moth-eaten margins of an undifferentiated carcinoma (Fig. 25-119C). On CT, note also that despite the extensive bone changes of fibrous dysplasia, the bone margins, including the facial nerve canal, are well preserved (Fig. 25-114).

Histiocytosis

Langerhans cell histiocytosis, formerly known as histiocytosis X, is a rare disease, probably a clonal neoplastic disorder, occurring primarily in the pediatric age group.[426, 427] Occasionally a less severe form occurs in adults. It includes a spectrum of disorders with histiocytic proliferation involving bone or soft tissues, namely, eosinophilic granuloma, Hand-Schüller-Christian's syndrome, and Letterer-Siwe disease, in order of prognosis from best to worst. In general, the patients with late-onset, unifocal bone lesions and without soft-tissue involvement have the best prognosis. Patients with eosinophilic granuloma, by definition, have only one or at most several bone

lesions, and the disease is generally benign, although progressive dissemination can occur (Figs. 25-116 and 25-117).[428] The treatment consists of surgery, irradiation, or chemotherapy (alone or in combination).[428]

In one series of 50 patients with disseminated histiocytosis, 18 had otomastoid involvement.[429] When the temporal bone is involved, the region of the EAC and mastoid appears to be a common location.[420, 428] Histiocytosis affects the petrous apex less frequently. Patients with middle ear and mastoid involvement present with symptoms such as otalgia and draining ear. Frequently, cases are diagnosed only after treatment with antibiotics fails to cure a suspected middle ear or mastoid infection. Early imaging findings also mimic inflammatory disease. In several reported cases, the bone margins were geographic and moderately well defined. ''Punched-out'' borders and beveled edges also may be found, and more irregular margins can be present especially after treatment.[430] On CT, enhancement within the lesion may be homogeneous or may occur only in the periphery.[430] On MR imaging, similar enhancement may be seen.[431]

THE PETROUS APEX

Petrous apex mass lesions are principally those that arise from within the petrous bone and expand the bone (e.g., cholesterol granuloma, intrapetrous epidermoid cyst, and intrapetrous carotid aneurysm) and those that arise in the immediate vicinity of the petrous apex and secondarily erode or invade the apex (e.g., chondrosarcoma from the petroclival junction, meningioma, trigeminal schwannoma, and intradural epidermoid).

Chondrosarcoma (Fig. 25-84), meningioma (Figs. 25-15 and 25-16), trigeminal schwannoma (Figs. 25-28 and 25-29), and intradural epidermoid cyst (Fig. 25-20) all can possess components in both the posterior and middle cranial fossae, straddling the petrous tip.[244] Frequently the posterior fossa component is intradural, and the middle fossa component may be either intradural, on the medial floor of the middle cranial fossa or in Meckel's cave, or extradural, extending into the cavernous sinus and sphenoid. These primarily CPA tumors are important considerations in the differential

diagnosis of petrous apex masses, but all except chondrosarcoma have been described at some length in the section Differential Diagnosis of Tumors of the Internal Auditory Canal and the Cerebellopontine Angle and therefore are not discussed further in this section.

The petrous apex also may be invaded by direct extension of jugular paragangliomas (Figs. 25-73 and 25-77) and nasopharyngeal carcinomas (Fig. 25-85), usually along the petrooccipital fissure, which is immediately superior to the fossa of Rosenmüller. For a complete differential diagnosis, systemic diseases and malignancies also need to be considered.

Two pitfalls have trapped the unwary, primarily on MR imaging: (1) asymmetric pneumatization of the petrous apex and (2) unilateral retention of secretions in apical air cells.[432] In the first instance, there is unilateral hyperintensity on T1-weighted images, from marrow of the nonpneumatized petrous apex, which fades in signal intensity on T2-weighted images, paralleling the signal intensity of fat. The use of fast spin-echo sequences leaves fat with significant signal on the T2-weighted images. This can confuse the issue, but the addition of a fat-suppression pulse clarifies the situation. In the second instance, there is unilateral hyperintensity on T2-weighted images from retained secretions that are usually hypointense on T1-weighted images, paralleling the signal intensity of fluid or mucus. Both of these conditions have been mistaken for tumors on MR imaging. CT usually resolves the question. Unlike true cysts or tumors, neither of these conditions shows bone erosion or expansion.

In contrast with lesions in the IAC, the geniculate fossa, or the tympanic cavity, which are frequently small when first seen, lesions in the petrous apex usually attain considerable size before causing cranial nerve symptoms. They are thus readily apparent on CT or MR imaging. However, besides localization and characterization, an important task for the radiologist is the preoperative differentiation between cystic and solid lesions (Table 25-11). Whereas solid lesions of the petrous apex require biopsy to determine appropriate treatment and extensive surgery if resection is indicated, cysts can be simply and definitively treated by drainage and permanent fistulization if a proper preoperative diagnosis is made.[385, 433, 434] MR imaging is generally used for the initial detection of such lesions, and CT with bone detail is used for surgical planning.

Cholesterol Granuloma (Cysts)

Cholesterol granuloma of the petrous apex has also come to be known as cholesterol cyst or giant cholesterol cyst (Fig. 25-106 and Table 25-11).[383–387, 435] *Cholesterol granuloma* is a term that emphasizes the histopathologic features of the lesion, and *cholesterol cyst* is a term that better describes the gross appearance of the lesion. Cholesterol cyst is the most common primary petrous apex lesion.[383, 384]

Cholesterol cysts possess a fibrous lining that may or may not be complete. The lining contains multinucleated giant cells with cholesterol crystals in acicular (needle-shaped)

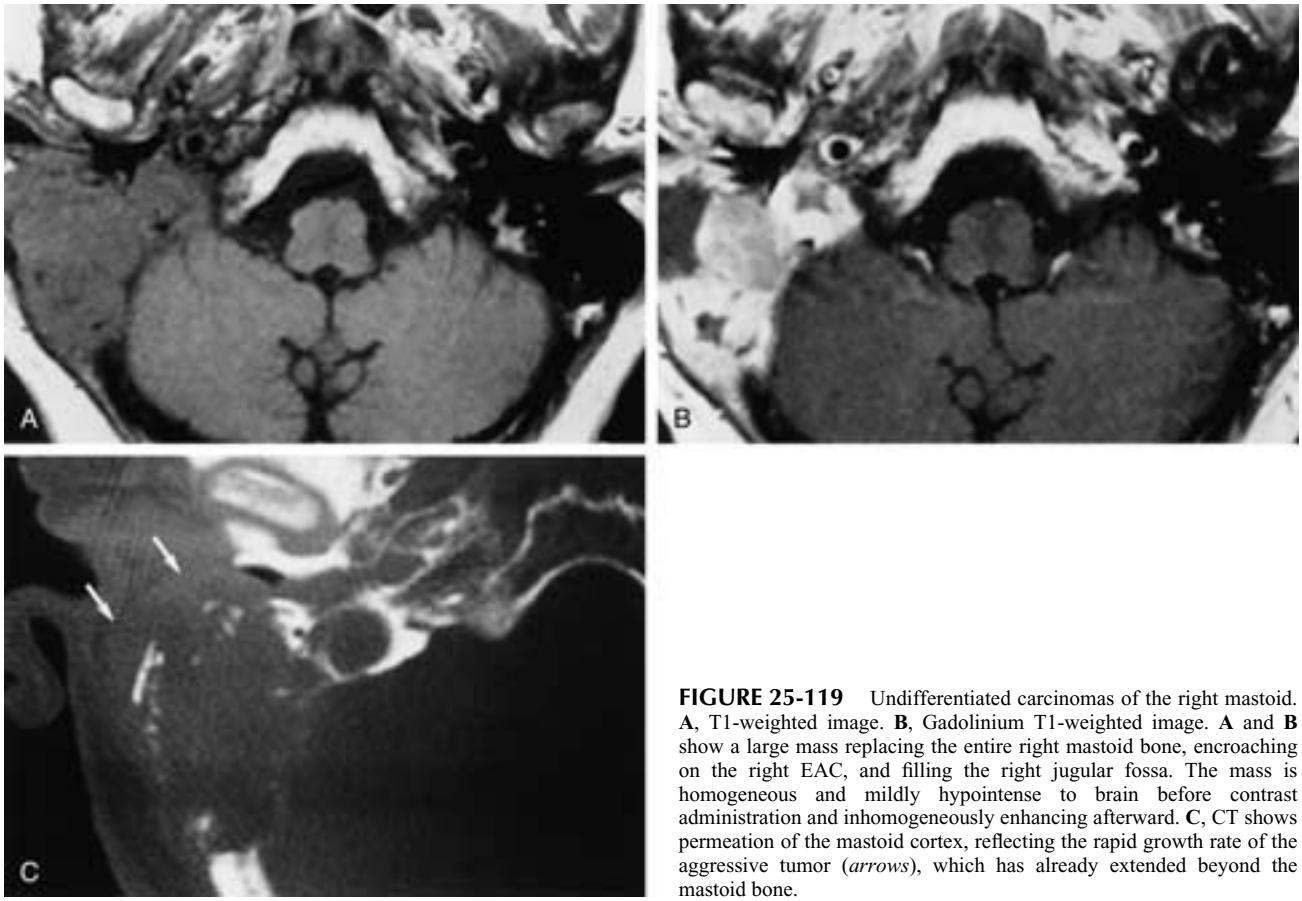

FIGURE 25-119 Undifferentiated carcinomas of the right mastoid. **A**, T1-weighted image. **B**, Gadolinium T1-weighted image. **A** and **B** show a large mass replacing the entire right mastoid bone, encroaching on the right EAC, and filling the right jugular fossa. The mass is homogeneous and mildly hypointense to brain before contrast administration and inhomogeneously enhancing afterward. **C**, CT shows permeation of the mastoid cortex, reflecting the rapid growth rate of the aggressive tumor (*arrows*), which has already extended beyond the mastoid bone.

clefts, blood vessels, fibrous tissues, red blood cells, hemosiderin, and chronic inflammatory cells. The content of the cyst is a brownish liquid glistening with cholesterol crystals and containing a brownish sediment.[382, 384] The contralateral petrous apex is usually well pneumatized, suggesting that these cysts arise in pneumatized apices (Fig. 25-106). Obstruction of the ventilation outlet has been theorized as the initiating cause of repetitive cycles of hemorrhage and granulomatous reaction.[436]

Cholesterol cysts occur in young and middle-aged adults of both sexes. Most of the patients have had symptoms for about 2 years.[382] Hearing loss, tinnitus, and hemifacial spasm are the most common complaints, but deficits of cranial nerves V, VI, IX, X, XI, and XII have all been encountered.[382, 384] Many of these deficits have been relieved by surgical decompression.[384, 437] Cholesterol cysts arise from within the petrous apex, posterior to the horizontal portion of the carotid canal, and they usually range from 2 to 4 cm in length at the time of their initial diagnosis.[382] On CT, they are sharply and smoothly marginated (Fig. 25-106). Generally ovoid in configuration, they expand the petrous apex, especially posteriorly, where the overlying bone is often paper thin or absent. Where bone is still present, the internal margin of the lesion is often sclerotic. The abutting portions of the carotid and jugular walls may be absent, the horizontal carotid canal is often bowed, and the adjacent occipital and sphenoid bones are commonly remodeled.[382] The lesions are approximately isodense with brain, and are homogeneous and free of calcium. They show no contrast enhancement except for a thin, smooth peripheral rim, which has variously been interpreted as representing either the capsule or the overlying dura.[382, 383]

On MR imaging, these lesions are strongly hyperintense on both T1-weighted and T2-weighted images. They frequently contain nonhomogeneous hypointense substances most likely representing hemosiderin from previous hemorrhage (Fig. 25-120).[386, 387] Some of them show a

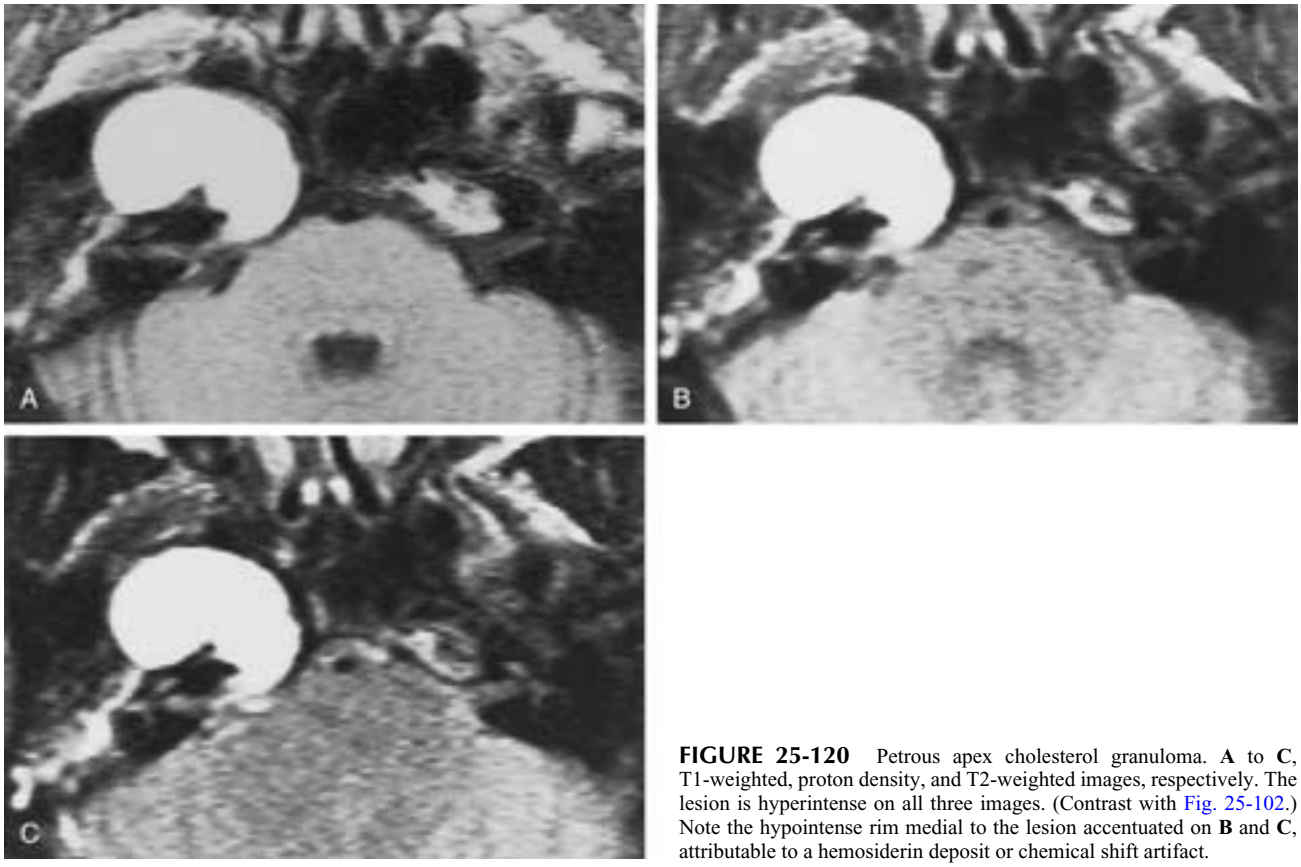

FIGURE 25-120 Petrous apex cholesterol granuloma. **A** to **C**, T1-weighted, proton density, and T2-weighted images, respectively. The lesion is hyperintense on all three images. (Contrast with Fig. 25-102.) Note the hypointense rim medial to the lesion accentuated on **B** and **C**, attributable to a hemosiderin deposit or chemical shift artifact.

hypointense rim on both T1-weighted and T2-weighted images.[387] Peripheral magnetic susceptibility on gradient-recalled echo sequences and central evidence of aliphatic protons on chemical shift imaging add specificity to the diagnosis.[387]

Epidermoid Cysts

Epidermoid cysts (or tumors) are also called primary cholesteatomas. They are less common in the petrous apex than in the supralabyrinthine region.[341, 363] Congenital intrapetrous epidermoid cyst is much rarer than cholesterol cyst. They are ''cysts,'' but they contain solid material and are usually treated by complete surgical resection with removal of the entire cyst wall to prevent recurrence, rather than by simple drainage and fistulization. Their preoperative differentiation from cholesterol granulomas (cysts) is therefore important.

Epidermoid cysts possess a capsule of stratified squamous lining and contain desquamated keratin, which appears grossly to be whitish friable material. As the desquamated keratin accumulates, the mass slowly expands. Thus, on CT, they appear as homogeneous, nonenhancing, sharply defined, ovoid expansile lesions (Fig. 25-101), like cholesterol cysts (Fig. 25-106).[19, 363, 438] Some epidermoid cysts appear hypodense and some isodense to brain. Hence, on CT, they may or may not be distinguishable from cholesterol cysts, which are isodense to brain.

Because of the rarity of intrapetrous epidermoid cysts, limited information exists in the literature on their MR imaging findings.[363] However, in two cases they were between CSF and brain in intensity on T1-weighted images, with a capsule isointense to brain (Fig. 25-101). A layered appearance may be present in the periphery on off-center sections. On T2-weighted images, they are strongly hyperintense to brain, but perhaps less so than cholesterol cysts.

Mucoceles

Mucoceles are lined with cuboidal or columnar epithelium and contain mucus. Petrous apex mucoceles are even rarer than petrous apex epidermoid cysts, and their CT and MR imaging appearances rarely have been documented in the literature.[380, 381, 439] They are also sharply defined, ovoid, expansile, nonenhancing masses. MR imaging of a single case shows hypointensity on T1-weighted images with a thin enhancing rim and hyperintensity on T2-weighted images (Fig. 25-121).[381] Thus it appears very similar to a congenital epidermoid cyst (Fig. 25-101).

Carotid Artery Aneurysms

Giant aneurysms from the intrapetrous horizontal carotid canal are extremely rare, but for obvious reasons they are extremely important in the differential diagnosis of petrous lesions.[237, 440] They also appear as well-defined ovoid, expanding masses. However, as with the intracranial giant aneurysms described earlier, their internal appearances vary considerably according to the extent of mural thrombus formation.[234]

On CT, a mural thrombus is isodense and nonenhancing, and the patent lumen shows a rapid rise and decline in enhancement. On MR imaging, a laminated mural thrombus shows varying signal intensities and the patent lumen appears as a signal void.[235–237] Flow-related enhancement may present confusing signals. Carotid artery aneurysms may be treated surgically or with transvascular techniques.[441, 442]

Chondrosarcomas

Primary intracranial cartilaginous tumors are rare.[18, 443, 444] Yet, chondrosarcoma is probably the most common primary malignant neoplasm in the region of the petrous apex. Affected patients range from children to the elderly.[445]Among its histologic subtypes, conventional is the most common.[217] The much rarer mesenchymal and dedifferentiated subtypes are more vascular, more aggressive, and less favorable in prognosis.[217]

Arising from embryonal rests in the skull base, chondrosarcomas tend to occur off midline, along synchondroses in the parasellar or the CPA region, but occasionally they may overlap in location and radiologic appearance with chordomas, which arise from notochordal remnants and typically occupy the midline.[446, 447] Since the time Heffelfinger et al. introduced the concept of a chondroid subtype of chordoma, pathologists often had difficulty differentiating it from the myxoid variant of chondrosarcoma.[130, 448] Over the years, controversy raged as to whether the two entities may not in fact be one.[130, 449] However, recent evidence such as results from cytokeratin stains seems to indicate that chondroid chordoma indeed exists and differs from myxoid chondrosarcoma, although over the years errors in diagnosis appear to have been made.[450] The entity of laterally placed chordoma probably has been overdiagnosed, or perhaps it never truly existed.[451] Hence before accepting a diagnosis of chondrosarcoma or chordoma, one should be aware of the criteria on which the diagnosis is based.

Most chondrosarcomas are centered more along the petrosphenoidal and petrooccipital fissures than within the petrous apex itself. Both chondrosarcoma and chordoma cause bone destruction and enhance mildly to moderately on CT, and both may contain calcifications.[443, 446, 452] On MR imaging, both are usually low to intermediate in signal intensity on T1-weighted images and hyperintense on T2-weighted images (Fig. 25-84).[445, 446, 452] Typically they are relatively homogeneous on T1-weighted images but heterogeneous on T2-weighted images (Fig. 25-84).[445] Their postcontrast enhancement is marked but may be heterogeneous (Fig. 25-84). The marked hyperintensity and heterogeneity on T2-weighted images, if present, may help to distinguish chondrosarcoma from other malignancies in the region such as myeloma (Fig. 25-122) and nasopharyngeal carcinoma (Fig. 25-85), which are less hyperintense and more homogeneous.

Compared with meningiomas, chondrosarcomas enhance less on CT and cause bone destruction rather than sclerosis or hyperostosis (Fig. 25-13).[443] However, very rarely, intradural chondrosarcoma overlying the petrous apex may extend into the posterior and middle cranial fossae, with CT

and MR imaging appearances suggestive of a meningioma.[244] Locally invasive chondrosarcomas may be treated with surgery using the infratemporal fossa approach or with radiation therapy.[8, 301, 446, 453–455]

A chondroblastoma, an uncommon benign tumor, may be indistinguishable from a chondrosarcoma on CT or MR imaging.[411]

Endolymphatic Sac Tumors

Endolymphatic sac tumors (ELST) are rare, locally invasive papillary cystadenomatous tumors causing sensorineural hearing loss and at times facial palsy.[412, 456, 457] Until pinpointed recently to the endolymphatic sac, they were often misdiagnosed as ceruminous neoplasms, metastatic thyroid and renal carcinomas, or choroid plexus papillomas.[458–461] ELST affect adults sporadically and are more common in patients with von Hippel-Lindau disease (vHL), an autosomal dominant multisystem disorder.[462, 463] In the latter case the tumors may be bilateral.[457, 462, 463] In the French registry of vHL, of 180 patients with cranial CT or MR imaging, 12 had findings of ELST, and 4 of the 12 had ELST as their initial manifestation of vHL (K. Marsot-Dupuch, personal communication).

ELST cause local destruction in the retrolabyrinthine petrous bone but may extend into the medial mastoid to invade the facial nerve or transdurally into the posterior cranial fossa (Fig. 25-104).[457, 462, 463] On CT, the bone margins are irregular, and intratumoral bone spicules are

Copyright © 2003, Mosby, Inc. All rights reserved.

commonly present.[376] On MR imaging, foci of hyperintensity are often found on precontrast T1-weighted images.[376, 464, 465] The treatment is wide local resection.[412]

Miscellaneous

Nasopharyngeal carcinoma is a frequent invader of the skull base.[217] Its posterior fossa extension tends to involve the petrous and occipital bones along the petrooccipital fissure.[466] In contrast to chondrosarcoma, nasopharyngeal carcinoma is likely to be more infiltrative, less bulky, and more homogeneous in its bone involvement (Fig. 25-85).

Xanthomas are specialized granulomas composed of lipid-laden, ''foamy'' histiocytes associated with cholesterol clefts and inflammation, usually associated with disorders of lipid metabolism such as hyperlipoproteinemia.[391] More commonly seen in the olecranon and Achilles tendon regions, they occasionally occur in the temporal bone. On CT, they appear as lytic masses containing many small calcific foci.[391] On MR imaging, xanthomas show an inhomogeneous, hyperintense mass with small, hypointense

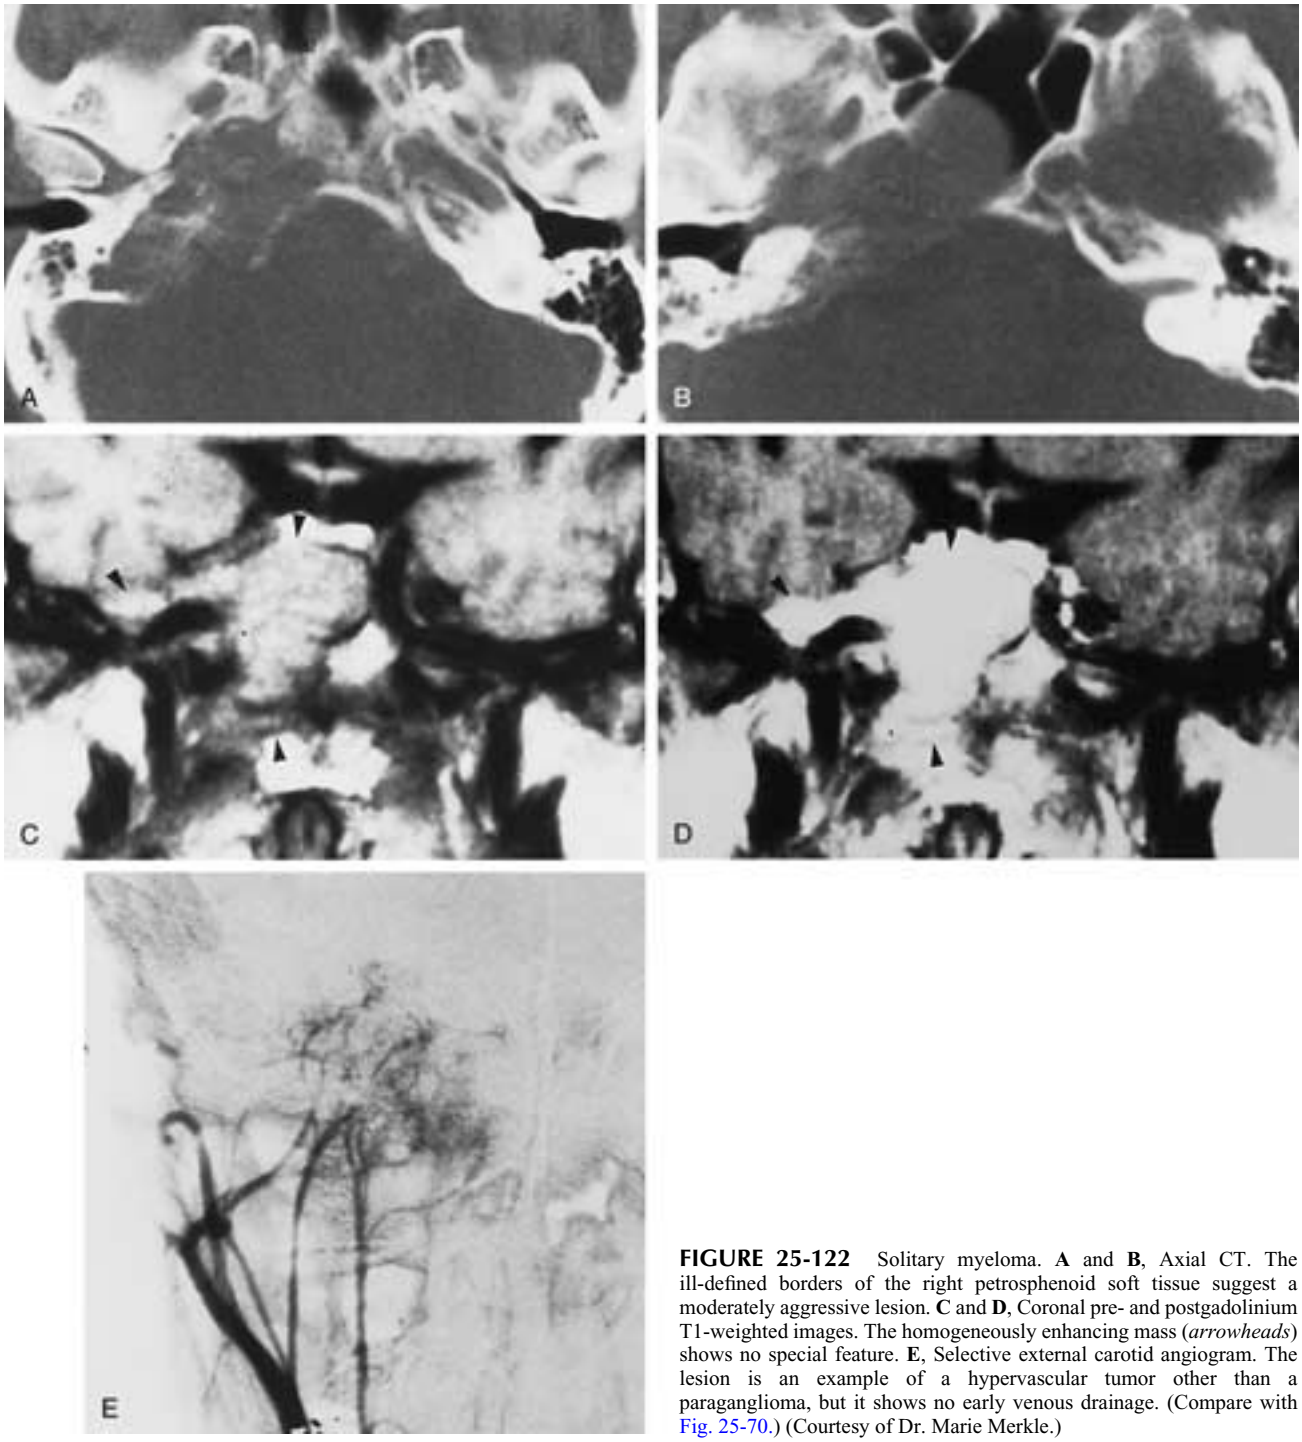

FIGURE 25-122 Solitary myeloma. **A** and **B**, Axial CT. The ill-defined borders of the right petrosphenoid soft tissue suggest a moderately aggressive lesion. **C** and **D**, Coronal pre- and postgadolinium T1-weighted images. foci on T1-weighted images and no appreciable contrast enhancement. On T2-weighted images, they are generally hypointense, with some hyperintense foci (Fig. 25-108).[467]

Myeloma (Fig. 25-122), lymphoma, metastases, giant cell tumors (Figs. 25-81 and 25-107), and other malignant tumors occasionally involve the petrous bone. The findings are nonspecific. Petrous apex abscess and skull base osteomyelitis (malignant external otitis) may also enter the differential diagnosis. Meningoceles can extend into the petrous apex usually from Meckel's cave. They can mimic expansile lesions of the apex. They follow CSF on various MR sequences (see Chapter 21).

Temporal Bone: Vascular Tinnitus

William W.M. Lo and M. Marcel Maya

ARTERIAL CAUSES
- Atherosclerosis
- Fibromuscular Dysplasia
- Dissection of the Carotid or Vertebral Artery
- Styloid Carotid Compression
- Petrous Carotid Aneurysm
- Aberrant Carotid Artery
- Laterally Displaced Carotid Artery
- Persistent Stapedial Artery
- Miscellaneous Arterial Anomalies

ARTERIOVENOUS CAUSES
- Paraganglioma
- Miscellaneous Vascular Head and Neck Tumors
- Paget's Disease
- Otosclerosis or Otospongiosis
- Cerebral Head and Neck Arteriovenous Malformation
- Dural Arteriovenous Fistula
- Direct Arteriovenous Fistula

VENOUS CAUSES
- Venous Tinnitus in Systemic Conditions
- Venous Tinnitis in Intracranial Hypertension
- Venous Tinnitus Caused by Transverse Sinus Stenosis
- Venous Tinnitus Associated with a Large or Exposed Jugular Bulb or Large Emissary Veins
- Idiopathic Venous Tinnitus

RADIOLOGIC INVESTIGATION

Tinnitus is a broad and complex subject concerning a symptom, rather than a syndrome or a disease.[1] The following discussion is confined to tinnitus from vascular causes.

Tinnitus may be caused by an intrinsic process such as vestibulocochlear disease, or it may have an extrinsic muscular or vascular cause.[1] Intrinsic tinnitus is subjective, being audible only to the patient, and extrinsic tinnitus is often objective, being potentially although not always audible to the examiner as well as to the patient. Although muscular tinnitus such as myoclonus of the palatal muscles or of the tensor tympani muscle can be pulsatile, it is not usually pulse-synchronous. By comparison, vascular tinnitus is always pulse-synchronous, and it is often a recordable sound audible to the examiner as a bruit.[1] However, whether a vascular tinnitus can be classified as objective may depend on the thoroughness of the search, the equipment used, and the level of ambient noise.[2, 3]

Tinnitus is a common complaint affecting some 30 to 40 million Americans.[4] In the majority of cases, it is subjective and may be associated with numerous conditions including conductive or sensorineural hearing loss and brainstem and cortical lesions.[1] When tumor, anomaly, or trauma is the suspected cause, the patient usually receives a radiologic evaluation. However, the majority of tinnitus cases are caused by Meniere's disease or syndrome, viropathies, drugs, allergy, noise, or systemic diseases, and the patients do not come to the attention of the radiologist.[5] Unfortunately, the cause of subjective tinnitus is often unclear, and effective treatment is lacking.

By contrast, although it is far rarer, objective tinnitus can usually be traced to a specific cause. In the case of vascular tinnitus, the radiologist tends to have a more active role in the diagnosis and treatment of this entity.

The causes of vascular tinnitus may be arterial, arteriovenous, or venous (Box 26-1). Some authors believe that paragangliomas are the most common cause of vascular tinnitus, but others cite dural arteriovenous fistula (AVF), idiopathic venous tinnitus, or idiopathic intracranial hypertension as being the most common causes.[3, 6–10] The experience of different authors likely reflects their individual expertise and referral patterns. Interestingly, in Remley et al.'s series of 107 patients with pulsatile tinnitus and a vascular retrotympanic mass, paraganglioma was the most common cause of subjective tinnitus, while dural and extracranial AVFs were the most common causes of objective tinnitus.[11]

BOX 26-1
VASCULAR TINNITUS: CAUSES

Arterial
Atherosclerosis
Fibromuscular dysplasia
Arterial dissection
Styloid carotid compression
Petrous carotid aneurysm
Aberrant carotid artery
Laterally displaced carotid artery
Persistent stapedial artery
Miscellaneous arterial anomalies
Arteriovenous (AV)
Paraganglioma (tympanicum, jugulare)
Miscellaneous vascular tumors
Paget's disease of bone
Otosclerosis or spongiosis
Cerebral AV malformation
Dural sinus AV fistula
Direct AV fistula
Venous
Chronic anemia
Pregnancy
Thyrotoxicosis
Hypertensive patients on vasodilators
Intracranial hypertension
Transverse sinus stenosis
Idiopathic venous tinnitus with or without large or exposed jugular bulb or large emissary vein

ARTERIAL CAUSES

The arterial causes of tinnitus include abnormalities in the lumen and abnormalities in the course. Aberrant arteries are rare but exceedingly important because of the hazards of mistreatment they invite when mistaken for tumors. They are discussed in greater detail in Chapter 21.

Atherosclerosis

Atherosclerotic plaques may produce turbulence of carotid flow and occasionally cause pulsatile tinnitus. However, in proportion to its high prevalence as a cause of asymptomatic carotid bruit, atherosclerosis is not a common cause of symptomatic pulsatile tinnitus.[12] This may be because the stenosis or luminal irregularity usually lies at the origin of the internal or external carotid artery, distant from the petrous bone.[13] Nonetheless, some cases have been reported.[14–17] In a report of eight patients with objective tinnitus caused by atherosclerotic carotid artery disease, tinnitus was the presenting symptom in five; however, no patient in the series required surgery or angioplasty for relief of symptoms.[15] On rare occasions, contralateral carotid artery stenosis or occlusion, or stenosis in the proximal brachiocephalic arteries, have also been reported as causes of pulsatile tinnitus.[18–21] Transluminal angioplasty and stenting may be performed on those lesions that are not readily accessible to surgical endarterectomy.[22, 23] Transmitted cardiac murmurs have also been implicated.[3]

Fibromuscular Dysplasia

Among the stenotic arteries, fibromuscular dysplasia (FMD), a segmental nonatheromatous, noninflammatory angiopathy of unknown etiology, is probably the most important cause of pulsatile tinnitus.[24–30] FMD, seen in 0.5% to 0.6% of carotid angiograms and autopsies, is the second most common cause of extracranial carotid narrowing.[12, 25] It is due to a fibroblastlike transformation of the smooth muscle cells of the arterial wall in medium-sized muscular arteries.[26] The vertebral and renal arteries may also be involved, bilaterality is common, and some patients may have intracranial berry aneurysms.[27, 31] Genetic predisposition may be a factor in this disease.[26, 32]

Often an incidental angiographic finding, FMD occurs predominantly in middle-aged women, many of whom are asymptomatic.[25] FMD appears to be more common than atherosclerosis as a cause of pulsatile tinnitus. This may be due to the fact that the stenosis in FMD is usually high in the cervical internal carotid artery at the level of the first and second cervical vertebrae, and the resultant turbulence is readily transmitted into the petrous bone.[13] Next to cerebral ischemic or hemorrhagic symptoms (such as headache, transient ischemic attack, stroke, and subarachnoid hemorrhage), pulsatile tinnitus is the most common complaint.[33] Among patients with symptoms of carotid FMDs, one third or more name pulsatile tinnitus as a presenting symptom, and in some patients this may be the primary complaint (Fig. 26-1).[24, 26, 33] Spontaneous dissection (Fig. 26-2B) or arteriovenous fistulization superimposed on carotid FMD may also precipitate pulsatile tinnitus, and rarely, vertebral FMD has caused pulsatile tinnitus.[29, 34, 35]

The classic angiographic appearance of FMD is the ''string of beads'' pattern, which is found in 85% of carotid FMD (Fig. 26-2A).[36] The less common patterns are tubular stenosis and semicircumferential narrowing. The accuracy of magnetic resonance angiography (MRA) in detecting FMD (Fig. 26-2) is unclear.[7, 37] However, magnetic resonance (MR) imaging has been shown to help distinguish tubular FMD from arterial dissection and arterial hypoplasia.[38]

Besides surgery and antiplatelet therapy, transluminal angioplasty has been successful in treating FMD.[28, 32, 33, 39–42] However, because most patients follow a benign course, treatment should not be instituted in the absence of progressive cerebral ischemia unless the patient feels that the noise is incapacitating.[13, 25] A survey for possible intracranial aneurysm with MRA is strongly advisable because an associated aneurysm may pose a greater hazard to the patient than the FMD itself.[43] The differential diagnosis of FMD includes Ehlers-Danlos syndrome type IV and giant cell and Takayasu's arteritides.[44]

Dissection of the Carotid or Vertebral Artery

Dissection of the cervicocephalic arteries may be spontaneous or traumatic.[45] Spontaneous dissections, sometimes after trivial trauma, usually affect one or both of the cervical internal carotid arteries of a young to middle-aged adult, and the vertebral artery is occasionally involved.[46–49] The etiology of spontaneous dissection is unknown;

Copyright © 2003, Mosby, Inc. All rights reserved.

however, angiographic FMD is present in 10% to 15% of the patients.[46]

The majority of the patients complain of ipsilateral headache.[46, 49] Other common manifestations are focal cerebral ischemic symptoms (transient ischemic attack or stroke), oculosympathetic paresis (partial Horner's syndrome), and bruit.[49] Bruits, subjective or objective, are found in about 40% of the patients (Fig. 26-3).[50]

The angiographic findings include luminal stenosis, abrupt reconstitution of the lumen, dissecting aneurysm, intimal flap, slow flow, occlusion, and distal emboli.[51] MR imaging may show loss of flow void in occlusion and hyperintense signal from intraluminal hemorrhage.[52, 53] MRA, dynamic computed tomography (CT), and ultrasonography have all been used for evaluation of cervicocephalic arterial dissection.[54–61]

Though the efficacy of medical and surgical therapy is unclear, anticoagulant followed by antiplatelet therapy is commonly prescribed.[49, 53] A persistent dissecting aneurysm discharging emboli may be resected. Nearly all of the stenoses resolve, but many occlusions do not recanalize, and further dissections may occur in other cervicocephalic arteries.[48, 49, 51]

Styloid Carotid Compression

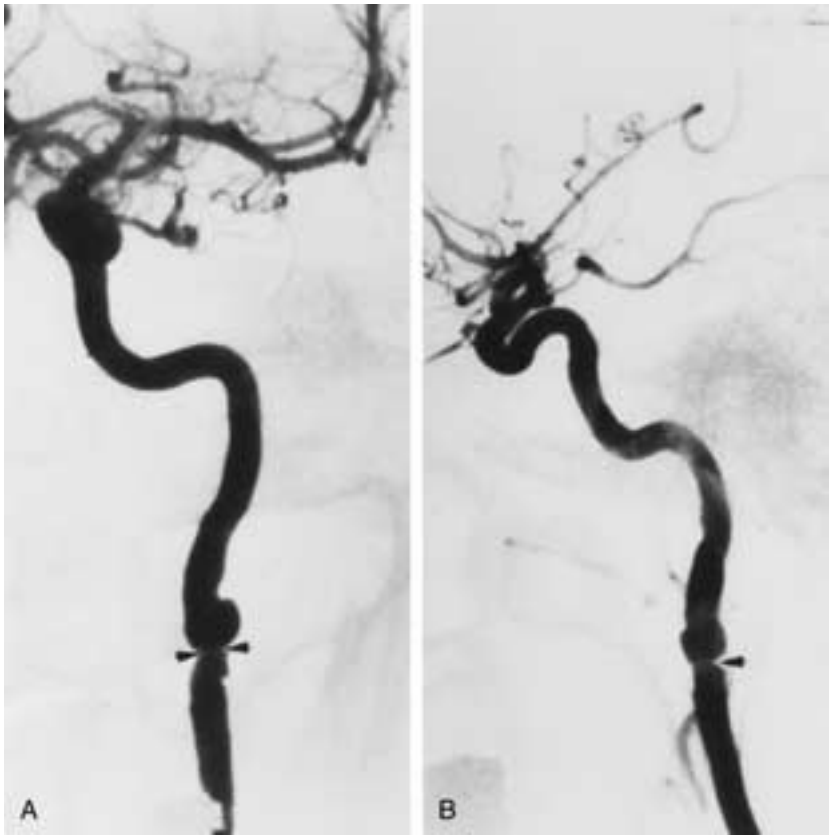
An elongated styloid process compressing a tortuous carotid artery has been reported as a cause of pulsatile tinnitus, but this appears to be a unique case.[6]

Petrous Carotid Aneurysm

Bruit may be the main complaint of patients with petrous carotid aneurysms.[62, 63] These aneurysms have been successfully treated with percutaneous transarterial embolization using detachable balloons or with surgical resection.[62, 64]

Aberrant Carotid Artery

The aberrant carotid artery is a rare anomaly, and patients who have one may be seen at almost any age.[65] Some of the patients experience pulsatile tinnitus and some have conductive hearing loss, but most have relatively mild symptoms that do not require treatment.[65] The aberrant carotid artery is extremely important in that clinically it simulates a paraganglioma in the middle ear.[65, 66] Many of the cases first reported were diagnosed after myringotomy or biopsy, often with disastrous consequences such as massive hemorrhage and hemiplegia.[67, 68] The aberrant artery enters the tympanic cavity through an enlarged inferior tympanic canaliculus and then undulates through the middle ear to enter the horizontal carotid canal through a dehiscence in the carotid plate.[65, 69] The ipsilateral ascending carotid canal is absent. CT is diagnostic (Figs. 26-4A and 26-5A). MRA may be used for confirmation (Fig. 26-4B) or for detection of a suspected associated aneurysm (Fig. 26-5B). Angiography is not necessary.[70]



VIEW IMAGE

FIGURE 26-1 Fibromuscular dysplasia of the internal carotid artery. Selective left internal carotid angiogram. **A**, Anteroposterior projection. **B**, Lateral projection. Critical noncircumferential web-like stenosis (*arrowheads*) immediately proximal to an eccentric diverticulum. The patient's major complaint was pulsatile tinnitus in the left ear aggravated by exercise and sufficient to cause sleeplessness. Symptoms were promptly relieved by percutaneous transluminal angioplasty. (From Hasso AN, Bird CR, Zinke DE, et al. Fibromuscular dysplasia of the internal carotid artery: percutaneous transluminal angioplasty. AJNR 1981;2: 175–180.)

VIEW IMAGE

FIGURE 26-4 Right aberrant carotid artery. **A**, High-resolution CT. The arrow indicates an aberrant artery coursing through the right tympanic cavity to enter the horizontal carotid canal through a dehiscence in the carotid plate. **B**, MRA 3D time-of-flight technique, maximum intensity projection, shows the typical sharp bend of a narrow aberrant artery (*arrow*) through the tympanic cavity.

Laterally Displaced Carotid Artery

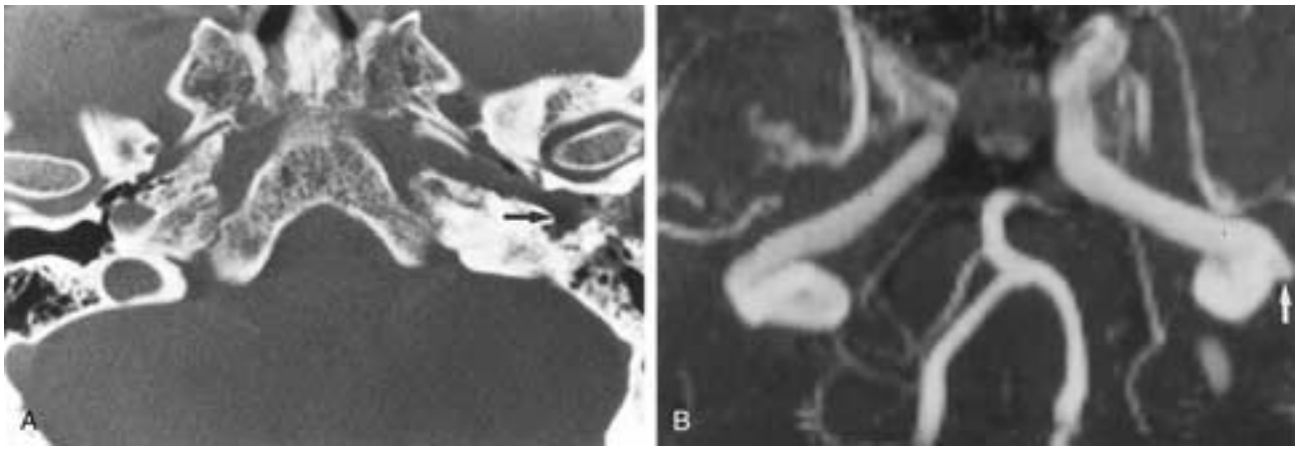
The laterally displaced carotid artery is one that knuckles into the tympanic cavity through a dehiscence of the bony carotid canal at the junction between the canal's vertical and horizontal segments.[71, 72] The artery does not take the long, narrow detour of an aberrant carotid artery, and it may be accompanied by an aneurysm. Although even rarer than the aberrant carotid artery and embryologically different, it does present the same hazards.

Persistent Stapedial Artery

A persistent stapedial artery large enough to be symptomatic is extremely rare. The artery courses from the infracochlear carotid through the stapedial obturator foramen and then enlarges the tympanic facial nerve canal en route to the middle cranial fossa to terminate as the middle meningeal artery.[69, 73, 74] The facial canal enlargement must not be mistakenly attributed to a facial nerve tumor. Characteristically, the ipsilateral foramen spinosum is absent.[73] CT is diagnostic (Fig. 26-6). The persistent stapedial artery may also accompany an aberrant carotid artery or a laterally displaced carotid artery, or it may originate from an ascending pharyngeal artery.[69, 72, 75]

Miscellaneous Arterial Anomalies

An anomalous artery 0.5 mm in diameter was encountered in the stria vascularis of the apex of the cochlea at postmortem histopathology. This anomaly appeared to be the cause of the patient's low-tone pulsatile tinnitus.[76] Such a vessel may be detectable with the recently available high-resolution, heavily T2-weighted, fast spin-echo or constructive interference steady-state MR imaging. Cross-compression of the eighth nerve in the cerebellopontine



VIEW IMAGE

angle by a persistent trigeminal artery was suggested as a cause of pulsatile tinnitus, although the evidence was circumstantial and venous tinnitus was not clearly excluded in the cases described.[77] Anterior communicating artery berry aneurysm has also been implicated in pulsatile tinnitus.[78] However, in view of the common coexistence of intracranial berry aneurysms with cervical internal carotid FMD, unless the latter has been specifically excluded, a causal relationship should not be assumed.[31]

ARTERIOVENOUS CAUSES

Arteriovenous (AV) causes include hypervascular tumors, hypervascular bone diseases, and high-flow shunts.

Paraganglioma

Paraganglioma is the second most common tumor of the temporal bone and the most common in the middle ear.[79] Characteristically hypervascular, it is one of the most common causes of pulsatile tinnitus. Whether involving the jugular bulb (glomus jugulare or jugulotympanicum) or confined to the middle ear or mastoid (glomus tympanicum), the majority of the paragangliomas first appear with pulsatile tinnitus (see Chapter 25).[80] The clinical differentiation between tympanicum and jugulare tumors is often difficult; however, CT with bone detail can be used to define the tumor and differentiate the tympanicum tumors, which require no angiography and only simple surgery, from the jugulare tumors, which require MR imaging, angiography, preoperative embolization, and extensive surgery.[81] An MR venogram (MRV) may also help detect jugular vein invasion.[82] MRA has not been shown to be reliable for assessment of tumor vascularity.

Miscellaneous Vascular Head and Neck Tumors

Other vascular tumors in the head and neck, both inside and outside the temporal bone, have been sporadically reported as causes of pulsatile tinnitus. These include, among others, AV malformation, capillary hemangioma, cavernous hemangioma, histiocytosis, jugular meningioma, adenoma, and cholesterol granuloma.[6, 11, 83–87]

Paget's Disease

Paget's disease affects 3% of the population over 40 years of age, men more often than women. The majority of cases are discovered incidentally.[88] Three histologic phases are recognized: (1) osteoclastic resorption, (2) osteoblastic regeneration, and (3) ''mosaic'' bone replacing the original bone.[88] Increase in the size and number of blood vessels and extensive AV shunting are frequently present.[88] In a series of 165 patients with skull involvement, 31 had tinnitus, 20 of whom had pulsatile tinnitus.[89] Two of the patients in the series had common carotid flow measurements determined, and values twice the normal rate were found. Proximal ligation of the hypertrophic arteries gives only temporary relief, but experience with transarterial embolization of the distal vessels does not appear to have been reported.[90]

Otosclerosis or Otospongiosis

Pulsatile tinnitus has been encountered in a small number of otosclerotic patients and is attributed to neovascularization and arteriovenous microfistulas.[3]

Cerebral and Head and Neck Arteriovenous Malformation

Cerebral AV malformations are congenital lesions consisting of a cluster of nonneoplastic dilated, tortuous arteries and veins without an intervening arteriole-capillary bed. Cerebral blood flow through large AV malformations may be markedly increased.[91, 92] The majority of the patients are young adults who most commonly have headache, subarachnoid hemorrhage, and seizures.[93] Although in one series as many as one third of the patients had cranial bruit on auscultation, few had pulsatile tinnitus as a complaint.[93] Rarely, cerebral AV malformations may cause a symptomatic bruit, and in at least one case pulsatile tinnitus was the primary complaint.[94, 95] Because the symptoms presumably result from high flow through the

Copyright © 2003, Mosby, Inc. All rights reserved.

sigmoid and petrosal sinuses, the malformation itself does not need to be in close proximity to the temporal bone. The same applies to large extracranial AV malformation in the head and neck.

Dural Arteriovenous Fistula

Most if not all dural arteriovenous fistulas (DAVFs) are acquired.[96] The pathogenesis is unclear, but some arise because of recanalization of a thrombosed dural sinus, with the transverse, sigmoid, and cavernous sinuses being the most common sites.[97–99] The blood supply may come from any of the meningeal branches of the external or even of the internal carotid arteries (Figs. 26-7 to 26-9). Delayed postoperative DAVFs have been reported after suboccipital craniotomy.[100–102]

Accounting for 10% to 15% of all intracranial AV malformations, DAVFs are rare.[103] However, they are a much more common cause of pulsatile tinnitus than are cerebral AV malformations, and in the experience of some clinicians they are the most common cause.[6, 10]

Nearly all patients with lateral or sigmoid sinus DAVFs, and some patients with cavernous sinus DAVFs, have pulsatile tinnitus and an audible bruit.[98, 101] In more than half of the patients in a Mayo Clinic series, the tinnitus stabilized or regressed, and spontaneous closures, usually of small fistulas, also were reported.[104–107] On the other hand, aggressive lesions may cause cerebral ischemic or hemorrhagic events or chronic increased intracranial pressure.[108, 109] The presence of veno-occlusive disease is a major determinant of the aggressiveness of a fistula.[42, 101, 104, 108]

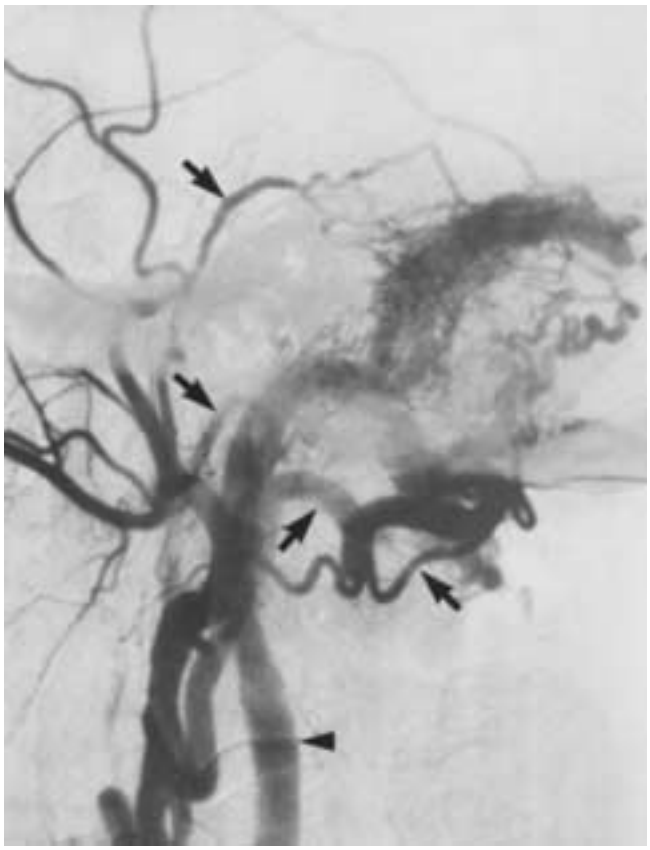

FIGURE 26-8 Large DAVF. Selective left external carotid angiogram. An extensive lesion along the transverse and sigmoid sinuses supplied by several hypertrophic external carotid branches (*arrows*) with rapid drainage down the internal jugular vein (*arrowhead*). The patient had temporary relief of pulsatile tinnitus after surgical ligation and, subsequently, partial relief of recurrent symptoms after transcatheter occlusive procedures.

FIGURE 26-7 Small DAVF. Selective left external carotid angiogram. A small lesion in the region of the inferior petrosal sinus (*arrow*) supplied by the ascending pharyngeal artery. The patient's pulsatile tinnitus diminished after a program of self-administered compression.

VIEW IMAGE

Although selective catheter angiography remains definitive in the evaluation of DAVF, three-dimensional (3D) time-of-flight MRA, which successfully demonstrated the fistula site in a series of six of seven cases, is a capable screening tool.[110] Nevertheless, while MR imaging effectively identifies infarct and hemorrhage in patients with veno-occlusive disease, neither MRA nor MR imaging is completely reliable in excluding dilated cortical veins, which is an important determinant for management.[110, 111]

A variety of treatment methods have been employed successfully.[98, 99, 112] In one series, self-administered external compression benefited about half of the patients without causing complications.[99] Patients who gain no relief from external compression can be treated by embolization with either isobutyl cyanoacrylate or polyvinyl alcohol sponges. The most problematic cases can be treated with a combination of embolization and surgery. In a series of 28 patients treated with these various methods, there were three strokes but no deaths, and transvenous embolization at the

The long arrow points to the right internal carotid artery; short arrows point to the enlarged right and normal left ascending pharyngeal arteries. A cluster of serpentine ''flow voids'' without an associated soft-tissue mass lies posterior to the right internal carotid and ascending pharyngeal arteries and between the open arrows. **B**, MRA 3D time-of-flight technique, maximum intensity projection. The hypertrophic right ascending pharyngeal artery (*curved arrow*) and a cluster of dilated vessels (*open arrow*) lie immediately medial, and a dilated inferior petrosal sinus (*arrow*) lies inferior to the right internal carotid artery.

fistula site may be indicated in some patients.[42, 99, 112] Surgical excision with packing of the sinus, now out of favor, also produced excellent results in most of the patients, but in a series of 27 patients there were two deaths by exsanguination.[98]

An analysis of 205 patients with DAVFs by Cognard et al. has shown that five angiographic patterns of venous drainage are highly predictive of the clinical course of the fistulas.[113] These patterns, with subtypes, form valuable guidelines for management. In essence, in the presence of antegrade dural sinus flow, only 1 of 84 patients developed intracranial hypertension and none experienced aggressive symptoms. Thus, such fistulas may be considered benign, and the patients should be treated only if incapacitated by their tinnitus. They may be monitored annually with Doppler studies for flow and should be reevaluated upon change of symptoms. In the presence of retrograde dural sinus flow, 8 of 27 patients developed intracranial hypertension; arterial embolization should be done in these patients to reduce flow and venous hypertension. With the development of retrograde leptomeningeal venous drainage (Fig. 26-10), hemorrhage and focal neurologic deficits occur; thus, occlusion or at least suppression of the leptomeningeal drainage by arterial embolization becomes mandatory. If necessary, transvenous occlusion or surgical resection of the sinus should be considered. Direct drainage of a fistula into the cortical veins carries an extremely high risk of hemorrhage and demands complete occlusion by any and all means.[113] Based on similar observations, Borden et al. proposed a simpler classification of three drainage patterns.[114, 115]

Recently, Davies et al. validated the value of both the Cognard and Borden classifications for predicting development of symptoms. They also confirmed that low-grade lesions tended to remain benign or resolve, while high-grade lesions tended to result in poor outcomes without therapeutic embolization and/or surgery.[116–118] Surgical disconnection yielded better results with far less mortality than excision.[118] Some groups, however, maintain that the variability in degrees of sinus occlusion is a progressive process in DAVFs, and hence that all such lesions should be treated.[119]

Direct Arteriovenous Fistula

Direct AV fistulas (AVFs) occur most often in the vertebral artery, but they may also involve the internal carotid artery or a branch of the external carotid artery. In the experience of some clinicians they are usually due to trauma, but in the experience of others they are more often spontaneous.[42, 120] The vertebral artery in its course through the foramen transversarum from C6 through C2 is closely

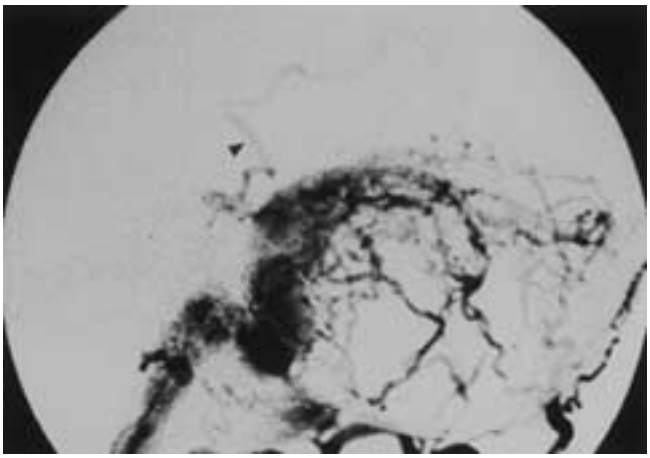

FIGURE 26-10 Large DAVF. Superselective occipital angiogram shows rapid antegrade drainage into the sigmoid sinus and down the internal jugular vein, and retrograde leptomeningeal reflux into the anastomotic lateral mesencephalic vein (*arrowhead*), a risk factor for intracranial hemorrhage not apparent on MRA.

surrounded by a venous plexus and is thus prone to develop AVFs when subjected to penetrating trauma (Fig. 26-11). Stab and bullet wounds are the most common causes.[121] Iatrogenic causes include direct vertebral puncture for angiography and anterior cervical discectomy.[122, 123] Spontaneous development occurs in neurofibromatosis 1 and FMD, as well as without specific underlying disease.[124–126] Tinnitus is the usual complaint in patients with vertebral AVF, and endovascular occlusion is the treatment of choice.[120, 127]

Traumatic AVF of the internal carotid artery usually develops in the cavernous sinus, where it is closely surrounded by a venous plexus.[128] Spontaneous carotico-cavernous fistulas may occur in fibromuscular dysplasia, Ehlers-Danlos syndrome, or neurofibromatosis.[1, 35, 42, 129] Ophthalmic symptoms and signs and pulsatile tinnitus are present in most of the patients. For vertebral AVFs, transarterial balloon embolization is the treatment of choice. Scalp AVFs also may cause pulsatile tinnitus.[42, 130, 131]

VENOUS CAUSES

Laminar flow is silent, and turbulent flow creates noise. When the noise exceeds the masking capability of the ear, it becomes venous tinnitus to the patient and may be audible to the examiner as a continuous bruit.[132] A venous bruit is usually heard around the ear. It should be distinguished from a venous hum, which can be elicited over the lower jugular vein in about half of normal subjects and in 80% of pregnant women.[133]

Venous tinnitus is invariably heard on the side of the dominant jugular vein.[8, 134, 135] Because the jugular fossa is larger on the right twice as often as it is on the left, it follows that the majority of venous tinnitus is heard on the right.[8, 134, 136]

Venous tinnitus is heard as a continuous murmur accentuated in systole. It is abolished by light pressure on the ipsilateral jugular vein and is accentuated by pressure on the contralateral vein. The symptom decreases when the head is rotated toward the involved side, and it increases when the head is turned away. Depending on its severity, venous tinnitus may or may not be audible to the examiner.[8]

Venous Tinnitus in Systemic Conditions

Venous tinnitus may be heard in conditions of hyperdynamic systemic circulation such as chronic anemia, pregnancy, and thyrotoxicosis.[132, 134, 137, 138] Hypertensive patients taking an angiotensin-converting enzyme inhibitor or a calcium channel blocker to reduce peripheral vascular resistance may rarely experience pulsatile tinnitus as a side effect.[15] Venous tinnitus in systemic conditions disappears as the underlying condition resolves.

Venous Tinnitus in Intracranial Hypertension

Headaches and blurring of vision are the predominant symptoms of intracranial hypertension, but venous tinnitus may also be a symptom.[139, 140] The pathogenesis of tinnitus in intracranial hypertension is unknown, but it is clearly and directly related to cerebrospinal fluid (CSF) pressure, and compression of dural sinuses by transmitted intracranial arterial pulsations has been postulated to be the mechanism.[15] Drainage of CSF by lumbar puncture promptly relieves the tinnitus.

Occasionally, pulsatile tinnitus can be a prominent symptom of intracranial hypertension resulting from a variety of causes.[42, 141, 142] These include aqueductal stenosis, Chiari I malformation and pneumocephalus.[143, 144] In some cases of idiopathic intracranial hypertension (IIH), also called benign intracranial hypertension and pseudotumor cerebri syndrome, it can be the presenting symptom or even the only symptom.[140, 142, 145, 146]

IIH is a syndrome characterized by increased intracranial pressure without focal neurologic signs, except for an occasional sixth nerve palsy.[139] The diagnosis is made by exclusion of lesions such as hydrocephalus, mass, chronic meningitis, dural sinus thrombosis, and hypertensive and pulmonary encephalopathy.

Patients suffering from pulsatile tinnitus from IIH tend to be young, obese women.[139, 141] In Sismanis et al.'s series of 31 patients, tinnitus was unilateral in 27 and bilateral in 4 and was also objective in 27 and subjective in 4.[141] On the CT and MR imaging scans performed to rule out

other causes of intracranial hypertension, more than half of the patients showed an empty sella or small ventricles.[141, 144, 147] A subsequent report by Sismanis and Smoker noted that papilledema was present in only 16 of 42 patients with CSF pressure over 200 mm Hg.[3]

The treatment must be directed to the underlying cause of the intracranial hypertension. In the case of IIH, acetazolamide, furosemide, and weight reduction are usually effective. Cases refractory to medical management may necessitate subarachnoid peritoneal shunting.[139–142]

Venous Tinnitus Caused by Transverse Sinus Stenosis

Venous tinnitus resulting from transverse sinus stenosis independent of DAVF is a diagnosis thus far seldom made.[7, 148, 149] Little information exists in the literature with regard to its etiology, natural history, or treatment. When warranted by incapacitating symptoms, transvenous stenting has been successfully performed.[149] True stenosis should be differentiated from arachnoid granulations in a dural sinus.[150] When there is unilateral transverse sinus thrombosis, the shifting of all of the blood flow to the contralateral side appears to be the cause of the contralateral pulsatile tinnitus.

Venous Tinnitus Associated with a Large or Exposed Jugular Bulb or Large Emissary Veins

Venous tinnitus has often been encountered in association with a large, high, or exposed jugular bulb.[134, 135, 137, 151] In view of the fact that the jugular bulb rises above the inferior tympanic annulus in 6% of the population and rises above the inferior border of the round window in 25%, and that venous tinnitus is much rarer, a high or large bulb in itself is not likely to be the cause of venous tinnitus.[152, 153] However, a large, high, or exposed bulb may indeed provide an environment conducive to the production of venous tinnitus. Furthermore, if a high bulb is exposed by dehiscence of the jugular plate and becomes visible as a bluish retrotympanic mass, it may be mistaken for a tumor.[65, 154, 155]

A laterally placed sigmoid sinus has been reported to be associated with pulsatile tinnitus.[156] Large emissary veins, probably of an incidental nature, may be seen in patients with venous tinnitus.[157, 158]

Venous tinnitus associated with a large, high, or exposed jugular bulb or a large emissary vein is essentially idiopathic venous tinnitus and can be managed similarly. Venous tinnitus associated with an exposed bulb has been successfully treated using a septal cartilage homograft over the dehiscent plate, but most patients do not require treatment.[159] Surgical lowering of the jugular bulb has been performed for high bulbs thought to be causing Meniere's disease and pulsatile tinnitus.[160]

Below the skull base, venous tinnitus can occur with an enlarged retromandibular vein and other vascular malformations in the periauricular region.

Idiopathic Venous Tinnitus

After exclusion of all specific causes, some cases of venous tinnitus remain unexplained and hence idiopathic. These cases usually involve women who are otherwise healthy, most of whom require only explanation and reassurance.[8, 135] The symptoms often resolve spontaneously.[14]

If the noise is truly intolerable, an external prosthetic clamp may be tried, and ligation of the vein under local anesthesia promptly relieves the symptom.[6, 132, 134] As an option, the optimal level of ligation may be tested by transvenous balloon occlusion; however, recurrences after ligation have been reported on the same or the contralateral side.[14, 134]

Moreover, jugular ligation risks causing intracranial hypertension. If it is to be attempted at all, IIH must first be excluded by lumbar puncture, contralateral venous drainage must be established and transverse sinus stenosis excluded by angiography or MRV, and an exposed jugular bulb must be excluded by otoscopy or high-resolution CT. In the absence of adequate contralateral drainage, jugular ligation may cause intracranial hypertension.[161] In the presence of dehiscence of the jugular plate, jugular ligation may cause herniation of the bulb into the middle ear. In such rare cases, a sigmoid-jugular bypass may be applied with or without jugular ligation.[8]

RADIOLOGIC INVESTIGATION

It is clear from the foregoing discussion that the causes of vascular tinnitus are diverse and numerous. To some patients, the symptom may be a mere nuisance; to others, it may herald a life-threatening disease. The natural history of the disease in different patients with the same diagnosis can vary widely. Management can also be complex, with some conditions requiring medical treatment, some requiring surgical treatment, some requiring endovascular treatment, some requiring a combination of treatments, and some requiring only explanation and reassurance with no other treatment.

The proper choice of imaging procedures is best tailored to the clinical findings of the patient.[3] Reliance on imaging procedures alone may cause failure to reach a diagnosis in some 40% of cases.[7] Direct communication with the referring clinician should be established, and, if necessary, the patient should be examined by the radiologist. The following imaging guidelines are suggested:

1. In the presence of a visible intratympanic or retrotympanic mass, noncontrast high-resolution CT is clearly the first examination of choice.[162] If an arterial anomaly, exposed jugular bulb, or intratympanic tumor is found, usually no further imaging is necessary. If destruction of the jugular plate suggests a glomus jugulare (jugulotympanicum) tumor, MR imaging or postcontrast CT may be done, followed by angiography, and, if indicated, a balloon occlusion test and preoperative embolization. An MRV with source images may be used in cases in which jugular vein invasion is questionable (see Fig. 25-74).[82]

Copyright © 2003, Mosby, Inc. All rights reserved.

2. When the tinnitus can be abolished by light pressure over the ipsilateral internal jugular vein, it is presumably of venous origin.[3] Systemic diseases, intracranial hypertension, and lateral sinus stenosis become the major considerations. Noncontrast MR imaging (to survey the brain) and an MRV (to define the posterior fossa dural sinuses, to confirm ipsilateral dominance, and to establish contralateral drainage in case of intervention) should suffice in most cases. Unless dural sinus angioplasty or stenting is indicated, patients in this group will rarely need angiography.
3. When a systolic bruit or machinery murmur is audible over the head or neck, indicating the presence of a stenotic artery or an arteriovenous shunt, MRA of the neck and head and noncontrast MR imaging of the head (to evaluate ischemic and hemorrhagic changes) will most likely yield a diagnosis.[7] If MRA fails to show a small fistula, gadolinium-enhanced MRA may be attempted.[110] Although MRA is less definitive than catheter angiography, the information that it provides can be most helpful for discussion and planning with the patients. If indicated, conventional angiography may then follow.

   As currently performed, MRA appears to be at least as accurate as ultrasonography in the evaluation of carotid bifurcation stenosis.[163] In addition, it allows evaluation of the upper cervical arteries and surveying for possible intracranial aneurysm in the same procedure.[164] CT angiography based on helical CT may be used for patients unable to undogo MR imaging.
4. If none of the aforementioned findings is present, the search is likely to be more difficult and the yield from imaging is likely to be low.[7] Nevertheless, significant lesions may still be detected by imaging.[7] Thus, MR imaging/MRA/MRV should be done to exclude intracranial abnormalities, high and deep-seated carotid stenosis or aneurysm, and dural sinus stenosis. Still, mild changes of FMD and small DAVFs may escape detection. High-resolution CT should be used to detect Paget's disease of the temporal bone, cochlear otospongiosis, and deep-seated tumors in the temporal bone. If these studies show no abnormality, the probability of significant disease becomes minimal. The benefit and risks of angiography must then be weighed carefully against the severity of the patient's symptoms.

Denervation Muscle Atrophy
Mandibular Division of the Trigeminal Nerve (V3)
Facial Nerve (VII)
Hypoglossal Nerve (XII)
Benign Masseteric Hypertrophy
Macroglossia

The oral cavity is the most ventral portion of the aerodigestive tract and is separated from the oropharynx by a ring of structures that includes the circumvallate papillae, the anterior tonsillar pillars, and the soft palate. From a clinical standpoint this anatomic subdivision is useful because malignancies, especially squamous cell carcinomas, in these two regions differ in their presentations, prognoses, and histologic grades.[1, 2] This chapter is primarily confined to the oral cavity, including the oral tongue (anterior two thirds of the tongue), floor of the mouth, lips, gingivobuccal and buccomasseteric regions, and the adjacent maxilla and mandible. The posterior one third of the tongue (base of the tongue) is discussed in Chapter 28. The muscles described in the following sections are summarized in Table 27-1.

NORMAL ANATOMY

The Oral Tongue

The tongue consists of symmetric halves separated from each other by a midline septum. The ''supporting skeleton'' of the tongue is composed of the lingual septum and the hyoglossus membrane, a thin, broad sheet suspended between the two minor tubercles of the hyoid bone. The fibrous lingual septum arises from the midline of the hyoglossus membrane and the middle of the hyoid bone, and because it is seen as a hypodense midline structure on CT scans through the tongue, it has also been referred to as the *midline low-density plane* (Figs. 27-1 and 27-2).[3, 4] Each half of the tongue is composed of muscular fibers arranged in various directions, which can be divided into extrinsic and intrinsic muscles. There are four interdigitating intrinsic muscles—the superior and inferior longitudinal, the transverse, and the vertical or oblique muscles—which make up the bulk of the tongue. The extrinsic muscles are those that have their origins external to the tongue itself, yet their more distal fibers interdigitate within the substance of the tongue. The extrinsic muscles provide attachment of the tongue to the hyoid bone, mandible, and styloid process of the skull base. The main extrinsic tongue muscles are the genioglossus, hyoglossus, and styloglossus muscles.[5, 6] Some authors also include the palatoglossus and superior pharyngeal constrictor muscles in their discussion of extrinsic tongue muscles.[7]

Intrinsic Muscles of the Tongue

The superior longitudinal muscle consists of a thin layer of oblique and longitudinal fibers that arise from the hyoglossus membrane and the fibrous lingual septum. The fibers fan out into a broad sheet, passing forward and outward to the edges of the tongue, just under the mucosa of the dorsum of the tongue.

The inferior longitudinal muscle has the same origin as the superior longitudinal muscle, but it is divided into two halves by the genioglossus muscle situated in the undersurface of the tongue. The inferior longitudinal muscle extends from the base to the tip of the tongue, lying medial to the hyoglossus and lateral to the genioglossus muscles.

The transverse muscles originate from the fibrous septum and fan outward to insert into the submucosal fibrous layer at the sides of the tongue. Intersecting with these transverse fibers are fibers from the vertical (oblique) muscles that extend from the upper surface to the undersurface of the tongue. These vertical fibers are encountered only at the borders of the anterior portion of the tongue.[7]

The intrinsic muscles are difficult to identify on CT, and fibers of the superior longitudinal muscle have, on occasion, been mistaken for a tumor.[4] However, these muscle bundles are easily appreciated on MR imaging because the low signal intensity muscle fibers are surrounded by the higher signal intensity of the fibrofatty supporting tissues (Fig. 27-3).[8] In particular, sagittal MR imaging demonstrates the full extent of the longitudinal muscles (Fig. 27-3C).[9]

The complex arrangement of the tongue musculature enables enunciation of various consonants. The superior longitudinal muscle tends to shorten the tongue and turn its tip and sides upward to render the dorsum concave. The inferior longitudinal muscle also shortens the tongue but pulls the tip down to render the dorsum convex. The transverse muscle fibers narrow and elongate the tongue, and the vertical fibers flatten and broaden the tongue. The intrinsic muscles of the tongue receive motor innervation from the hypoglossal nerve (XII).

Extrinsic Muscles of the Tongue

The Genioglossus Muscles

The paired genioglossus muscles originate via a short tendon from the superior genial tubercle on the inner surface of the mandible, just above the origin of the geniohyoid muscles. The fibers quickly fan out, the inferior fibers attaching via a thin aponeurosis to the body of the hyoid bone, the middle fibers coursing posteriorly, and the superior fibers directed upward and dorsally to insert into the entire length of the undersurface of the tongue from its base to its apex. Posteriorly, the genioglossus muscles are quite distinct from each other, separated by the midline lingual septum and fatty tissue, easily identified on both axial and coronal CT and MR images (Figs. 27-1 to 27-3). The two muscles are quite symmetric, measuring 9 to 11 mm in the transverse dimension at their intersection with the hyoglossus muscle.[10] More anteriorly, however, the fibers from the two muscles are less distinct and somewhat blended together as

Table 27-1
MUSCLES ASSOCIATED WITH THE ORAL CAVITY

Muscle Innervation	Action	Origin	Insertion	Motor
Superior longitudinal constrictor muscles	Hyglossal membrane and fibrous lingual septum	Edges of the tongue under dorsum mucosa, fanning out to a broad sheet	Hypoglossal nerve (XII)	Shortens the tongue and turns the lip and sides up to render the dorsum concave
Inferior longitudinal constrictor muscles	Hyglossal membrane and fibrous lingual septum but divided by genioglossus muscles and situated on undersurface of the tongue	From base to tip of the tongue medial to hyoglossus and lateral to genioglossus muscles	Hypoglossal nerve (XII)	Shortens the tongue but pulls tip downward to render the dorsum convex
Transverse muscles	Fibrous lingual septum	Fan out to insert into the submucosal fibrous layer at the sides of tongue	Hypoglossal nerve (XII)	Narrows and elongates the tongue
Vertical/oblique muscles	Upper surface of the tongue	Undersurface of the tongue	Hypoglossal nerve (XII)	Flattens and broadens the tongue
Genioglossus muscle	From the upper mental spines of the genial tubercles	Contacts its counterpart in the median plane and fans vertically into the tongue, inserted throughout its length; some inferior fibers reach the hyoid bone	Hypoglossal nerve (XII)	Acting together, the two muscles protrude the tongue; if one muscle is paralyzed, the tip of the tongue deviates toward the inactive side
Hyoglossus muscle	Body and greater horn of hyoid bone	Posterior one half of the side of the tongue	Hypoglossal nerve (XII)	Depresses the sides of the tongue and enlarges the cavity of the mouth
Styloglossus muscle	From tip of styloid process of temporal bone and adjacent part of stylohyoid ligament	Entire length of the side of the tongue, interdigitating with fibers of the hyoglossus muscle	Hypoglossal nerve (XII)	Pulls the tongue posterosuperiorly during swallowing
Mylohyoid muscle	Entire length of the mylohyoid line on inner surface of the mandible	Into a fibrous median raphe extending from the symphysis of the mandible to the body of the hyoid bone	Mylohyoid nerve branch of the inferior alveolar branch of the mandibular division of the trigeminal nerve (V3)	Raises the hyoid bone and tongue during swallowing and forms the muscular floor of the mouth
Anterior belly of the digastric muscle	Digastric fossa of the mandible just below the genial tubercles	United by an intermediate tendon with the posterior belly; bound to the upper border of the hyoid bone by a loop of fibrous tissue	Mylohyoid nerve branch of the inferior alveolar branch of the mandibular division of trigeminal nerve (V3). (*Note*: The posterior belly is innervated by the facial nerve [VII].)	Acting with its posterior belly, it raises the hyoid bone during swallowing; acting with the infrahyoid strap muscles, it fixes the hyoid bone to form a stable base on which the tongue can move
Geniohyoid muscle	From the lower mental spines of the genial tubercles, on the inner surface of mandible near the midline	The paired muscles course side by side on the superior surface of the mylohyoid muscle to insert onto the anterior body of the hyoid bone	Fibers from C1	Pulls the hyoid bone anterosuperiorly
Buccinator muscle	Outer surface of the alveolar processes of the mandible and maxilla corresponding to the three molar teeth; anterior margin of the pterygomandibular raphe	Fibers coverage toward the angle of the mouth where central fibers intersect each other, being continuous with the orbicularis oris, and upper- and lowermost fibers continuing into corresponding segments of the lip without decussation	Facial nerve (VII)	Used during mastication to press cheek against the teeth, thus preventing food from escaping into vestibule of the mouth
Masseter muscle	Inferior margin and deep surface of the zygomatic arch from the tubercle at its root posteriorly to the junction with the zygomatic process of the maxilla anteriorly	Lateral surface of the ramus and coronoid process of the mandible	Branch of the mandibular division of the trigeminal nerve (V3)	Raises the mandible and clenches the teeth; superficial fibers help protract the mandible

Table continued on following page

Table 27-1
MUSCLES ASSOCIATED WITH THE ORAL CAVITY *Continued*

Muscle Innervation	Action	Origin	Insertion	Motor
Medial pterygoid muscle	Superficial head arises from maxillary tuberosity; deep head arises from medial surface of the lateral pterygoid plate, deep to the lateral pterygoid muscle	Rough area between the mandibular foramen and angle of the mandible; its fibers essentially parallel those of the anterior masseter fibers	Branch of the mandibular division of the trigeminal nerve (V3)	Raises the mandible, assists in its protrusion, and slews the chin to the opposite side; acting alternately, the muscles produce a grinding movement
Lateral pterygoid muscle	Upper head arises from infratemporal ridge and infratemporal surface of greater wing of sphenoid bone; lower head arises from lateral surface of lateral pterygoid plate	Into front of the neck of the mandible and the articular disk through the capsule of the temporomandibular joint	Branch of the mandibular division of the trigeminal nerve (V3)	Together, the two muscles protrude the mandible and depress the chin, drawing the head of the mandible and the disk forward onto the articular tubercle; when one acts alone, the head of the mandible on that side is drawn forward, the mandible pivots around the joint, and the chin is slewed to the opposite side
Temporalis muscle	Floor of the temporal fossa and from temporal fascia	Summit and anterior margin of coronoid process and anterior margin of ramus; medial side of coronoid process down to junction of ramus with body of mandible behind the third molar tooth	Deep temporal branches of the mandibular division of the trigeminal nerve (V3)	Raises the mandible; posterior fibers retract the mandible after protraction

fascicles from one muscle cross the midline to interdigitate with those of the contralateral muscle.[7]

The Hyoglossus Muscles

The hyoglossus muscles are thin, flat quadrilateral muscles forming the lateral borders of the tongue. They arise from the greater cornua of the hyoid bone and course vertically, lateral to the genioglossus muscles, to insert into the sides of the tongue. In their posterosuperior aspect, fibers of the hyoglossus interdigitate with fibers of the styloglossus muscle (see the next section). The hyoglossus muscles are best seen on CT or MR imaging in the axial plane (Figs. 27-1 and 27-3A).[3] The normal transverse diameter of each muscle, measured in the axial plane, is 5 to 7 mm.[10]

The Styloglossus Muscle

The styloglossus muscle arises from the anterolateral surface of the styloid process of the temporal bone, near its apex, and from portions of the stylomandibular ligament. Passing downward and forward between the internal and external carotid arteries, it divides at the side of the tongue into two sets of fibers. The longitudinal fibers enter the side of the tongue near its dorsal surface, anterior to the hyoglossus fibers, and the more posterior oblique fibers interdigitate with fibers of the hyoglossus muscle.

The Palatoglossus Muscle

The palatoglossus muscle with its overlying mucosa forms the palatoglossal arch (anterior tonsillar pillar). The muscle arises from the oral surface of the palatal aponeurosis and the soft palate and extends laterally, forward, and downward to the palatine tonsil to insert on the dorsum and side of the tongue, its fibers blending with those of the styloglossus and transverse lingual muscles.

Motor and Sensory Innervation of the Tongue

The intrinsic and extrinsic muscles of the tongue all receive motor innervation from the hypoglossal nerve (XII), which courses between the mylohyoid and hyoglossus muscles. The palatoglossus muscle is innervated by the pharyngeal plexus. Adjacent to the hypoglossal nerve is the lingual nerve, a branch of the trigeminal nerve that carries sensory fibers from the anterior portion of the tongue. Special sensory taste fibers from the anterior two thirds of the tongue course with the lingual nerve over a short distance before they coalesce to form the chorda tympani nerve, which extends to the lateral skull base, traverses the middle ear, and joins the facial nerve. Special sensory taste fibers from the posterior one third of the tongue are supplied by the glossopharyngeal nerve (IX).

Floor of the Mouth

The floor of the mouth is a U-shaped structure covered by squamous mucosa. The primary muscles comprising the floor of the mouth are the mylohyoid muscles and their fibrous median raphe. Additional support is provided by the paired anterior bellies of the digastric muscles and the geniohyoid muscles (Figs. 27-2 and 27-3B). Surgically, the floor of the mouth is considered that space between

the mucosa of the floor of the mouth and the mylohyoid muscle sling. Caudal to this muscle but above the hyoid bone, the space is considered the suprahyoid neck.

The Mylohyoid Muscle

The mylohyoid muscle is a flat, triangular muscle that arises from the entire length of the mylohyoid ridge on the inner surface of the mandible and extends from the mandibular symphysis anteriorly to the last molar tooth posteriorly.[7] Posterior fibers course inferiorly to insert onto the body of the hyoid bone. The remaining middle and anterior fibers insert into the fibrous median raphe that runs between the mandibular symphysis and the hyoid bone, thus joining with fibers from the opposite side to form the U-shaped muscular floor of the mouth. The mylohyoid muscle sling is best demonstrated by CT and MR imaging in the coronal plane (Figs. 27-2 and 27-3B). The mylohyoid branch of the inferior alveolar nerve (a branch of the mandibular division of the trigeminal nerve [V3]) provides motor innervation to the mylohyoid muscle. Just before entering the mandibular foramen, the inferior alveolar nerve gives off the small mylohyoid nerve, which descends in a groove on the inner surface of the mandible, held in position by a fibrous membrane.[7]

There is a gap at the free posterior border of the mylohyoid muscle, between it and the hyoglossus muscle. It is via this gap that the submandibular gland wraps around the dorsal aspect of the mylohyoid muscle, with the deep lobe of the gland lying cranial to the muscle fibers and the superficial lobe lying on its external (caudal) surface.

The Digastric Muscle

The digastric muscle consists of two bellies. The anterior belly arises from the digastric fossa on the inner surface of the mandible, just below the genial tubercles. The posterior belly arises from the digastric fossa on the inner surface of the mastoid process of the temporal bone. The two bellies terminate in a central tendon that pierces the stylohyoid muscle and runs through a fibrous loop (lined with a synovial membrane) that is attached to the body and greater cornua of the hyoid bone. The two paramedian anterior digastric muscles lie just below (caudal to) the mylohyoid muscle sling and thus contribute to the muscular floor of the mouth. They are best seen on CT and MR imaging in the coronal plane. Like the mylohyoid muscle, the anterior belly of the digastric muscle is innervated by the mylohyoid branch of the mandibular nerve (V3). The posterior belly receives its innervation from the facial nerve (VII).

The Geniohyoid Muscle

Each geniohyoid muscle is a slender muscle that arises from the inferior genial tubercle on the inner surface of the mandible. It passes inferiorly to insert onto the anterior surface of the body of the hyoid bone. Closely approximated, the geniohyoid muscles lie just above the mylohyoid sling; this is best appreciated on CT scans and MR images obtained in the coronal plane. Because the geniohyoid muscles do not have interspersed fibrofatty tissue, as do the extrinsic muscles of the tongue, they may occasionally appear denser than the genioglossus muscles on CT. Motor innervation to the geniohyoid muscles is variably described to be from the hypoglossal nerve (XII), by the few fibers from C1 that course with the hypoglossal nerve until it crosses the internal carotid artery, or by motor fibers from both C1 and C2.[5–7, 11]

The Sublingual Region

Superomedial to the mylohyoid muscle, lateral to the genioglossus-geniohyoid muscles, and below the mucosa of the floor of the mouth is the primarily fat-filled sublingual area known as the *sublingual space* or *sublingual compartment of the submandibular space.* Based on its CT appearance, it is also referred to by some authors as the *lateral low-density plane* (see also Chapters 34 and 39).[3, 4, 12] This region is continuous with the submandibular region at the posterior margin of the mylohyoid muscle (Fig. 27-4A). Contents of this sublingual ''space'' include the deep portion and hilum of the submandibular gland, Wharton's duct, the anterior fibers of the hyoglossus muscle, and the lingual nerve, artery, and vein. On either side, the hyoglossus, styloglossus, and palatoglossus muscles form a slightly curved lateral muscular bundle in the sublingual space. Together these muscles are an important surgical

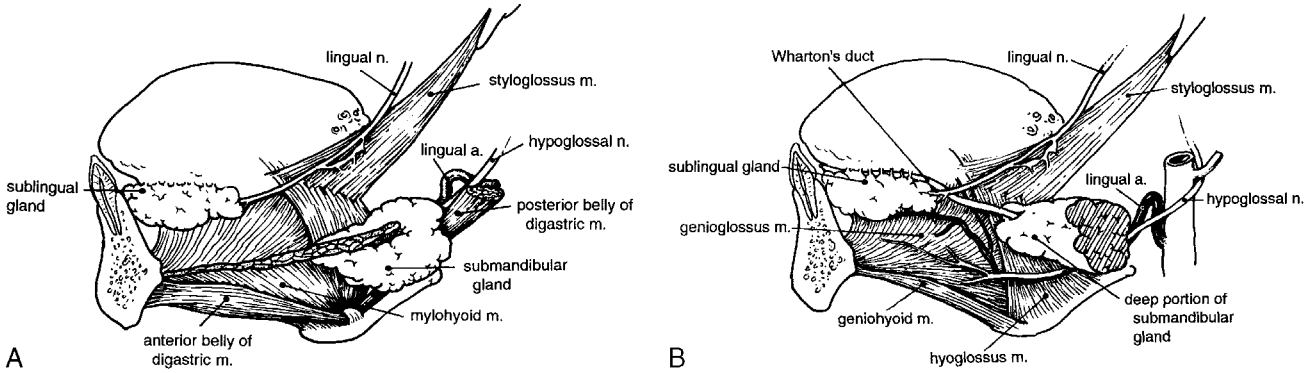

FIGURE 27-4 Diagram demonstrating normal structural relationships. **A**, Lateral view with the mylohyoid muscle in place. The mylohyoid muscle separates the anterior belly of the digastric muscle, which lies superficial, from the geniohyoid muscle, which lies on a deeper plane. The submandibular gland wraps around the posterior margin of the mylohyoid muscle, and its deep lobe enters the posterior aspect of the sublingual space. Note the fibrous loop that anchors the common digastric tendon to the hyoid bone. **B**, Lateral view of the oral cavity with the mylohyoid and digastric muscles removed. Note that Wharton's duct, along with the hypoglossal and lingual nerves, lies superficial to the hyoglossus muscle and the facial vessels lie on a plane deep to the muscle.

landmark to the anatomy of the sublingual region, as they separate Wharton's duct and the hypoglossal and lingual nerves, which lie laterally, from the lingual artery and vein, which course medially (Fig. 27-4B).[3] Wharton's duct arises from the deep portion of the gland and runs anteriorly, in contact with the hypoglossal and lingual nerves. Initially, it lies between the hyoglossus and mylohyoid muscles, and more anteriorly it lies between the genioglossus and mylohyoid muscles. The duct drains into the floor of the mouth, just lateral to the frenulum of the tongue.

Submandibular Space

Inferior to the mylohyoid muscle lies the submandibular space (also see Chapter 34). It is a fascially defined space except at the posterior margin of the mylohyoid muscle, where it is in continuity with the posterior aspect of the sublingual space and the anterior aspect of the parapharyngeal space (Fig. 27-4A). This communication permits easy spread of pathology among these spaces. The primary contents of the submandibular space are fat and the larger superficial portion of the submandibular gland. On either side, the anterior belly of the digastric muscle lies within the fat in a paramedian location, and the region between these two muscle bellies is referred to as the *submental portion of the submandibular space* or the *submental space* (Figs. 27-1E,F, 27-2 and 27-3B). This is a small triangular midline area in which the submental lymph nodes (level IA) reside. Submandibular lymph nodes (level IB) and branches of the facial artery and vein lie lateral to the anterior digastric muscle in the fat surrounding the superficial portion of the submandibular gland. The artery courses deep to the gland, while the vein runs superficially, just beneath the investing fascia. The vein is a useful landmark when evaluating submandibular region masses. Primary disease of the submandibular gland is never separated from the gland by the vein but displaces the vein laterally. However, lymphadenopathy and other soft-tissue masses that lie lateral to the gland are separated from the gland by the interposed vein.[13]

On CT, the normal submandibular gland is fairly homogeneous in appearance and may be of either a relatively fatty or soft-tissue attenuation. The density and enhancement of the two glands should be symmetric. If not, one gland is abnormal. On MR imaging, the normal submandibular gland has either a homogeneous or heterogeneous MR signal intensity, which is higher than that of surrounding muscle on both T1-weighted and T2-weighted images.[14]

Lips and Gingivobuccal Region

The lips are composed primarily of the orbicularis oris muscle, which is not a sphincter muscle but rather is composed of muscle fibers derived from multiple facial muscles that insert into the lips and some additional fibers proper to the lips themselves. Muscles that contribute to the orbicularis oris include the levator labii superioris alaeque nasi, levator labii superioris, levator anguli oris, zygomaticus major, depressor anguli oris, platysma, risorius, and buccinator muscles.[7] Motor innervation to the lips is supplied by branches of the facial (VII) nerve, and lymphatic drainage is primarily to the submental and submandibular lymph nodes (level I). The external surface of the lips is covered by keratinizing stratified squamous epithelium, and the internal surface is lined by nonkeratinizing stratified squamous mucosa.

The vestibule of the mouth separates the lips and cheeks, which are lined by buccal mucosa, from the teeth and gums. It is essentially a cleft into which drain the ducts of the parotid glands and the mucous glands of the lips and cheeks. The vestibule is bounded superiorly and inferiorly by reflections of the buccal mucosa onto the maxilla and mandible, respectively. The vestibule is continuous posteriorly with the oral cavity proper through an interval between the last molar tooth and the ramus of the mandible.

The gingiva is the mucosal covering and overlies both the medial (lingual) and lateral (buccal) aspects of the alveolar processes of the mandible and maxilla. The junction of the gingiva with the buccal mucosa is termed the *gingivobuccal sulcus* and is a common location for squamous cell carcinoma of the oral cavity. At times it may be difficult to determine if a lesion originates from the gingival or buccal mucosa. On imaging, instructing patients to ''puff'' their cheeks, thereby dilating the vestibule with air and separating these mucosal surfaces, is a useful maneuver for visualizing lesions in this area (Fig. 27-5). There is also a triangular area of mucosa posterior to the last mandibular molar tooth termed the *retromolar trigone.* This region covers the lower ascending ramus of the mandible, and it is another area in which squamous cell carcinomas commonly arise.

Buccomasseteric Region

The term *buccomasseteric region* refers to the masseter and buccinator muscles, the buccal space, and the inferior body of the mandible (Fig. 27-6).[15]

The masseter muscle is one of the muscles of mastication and is innervated by the masticator nerve, a branch of the mandibular division of the trigeminal nerve. Posteriorly, the muscle is largely covered by the superficial lobe of the parotid gland, and buccomasseteric pathology is often initially mistaken for parotid disease.

The buccinator (*buccina*, a trumpet) muscle, the major muscle of the cheek, is located external to the buccal mucosa. It is a deep muscle of facial expression that is innervated by a branch of the facial (VII) nerve. Its main function is to compress the cheeks (i.e., during mastication, playing the trumpet, etc.). The origin of this muscle is from the alveolar processes of both the maxilla and the mandible, opposite the sockets of the molar teeth, and the anterior border of the pterygomandibular raphe. The fibers of the buccinator muscle converge toward the angle of the mouth, where they blend and insert into the orbicularis oris muscle. The pterygomandibular raphe is a thick fascial band that extends between the hamulus of the medial pterygoid plate and the posterior border of the mylohyoid ridge of the mandible. Forming the line of attachment for the buccinator and superior pharyngeal constrictor muscles, the pterygomandibular raphe is the junction of the oropharynx and oral cavity, lying between the anterior tonsillar pillar and the retromolar trigone.[16] Malignancies in the retromolar trigone

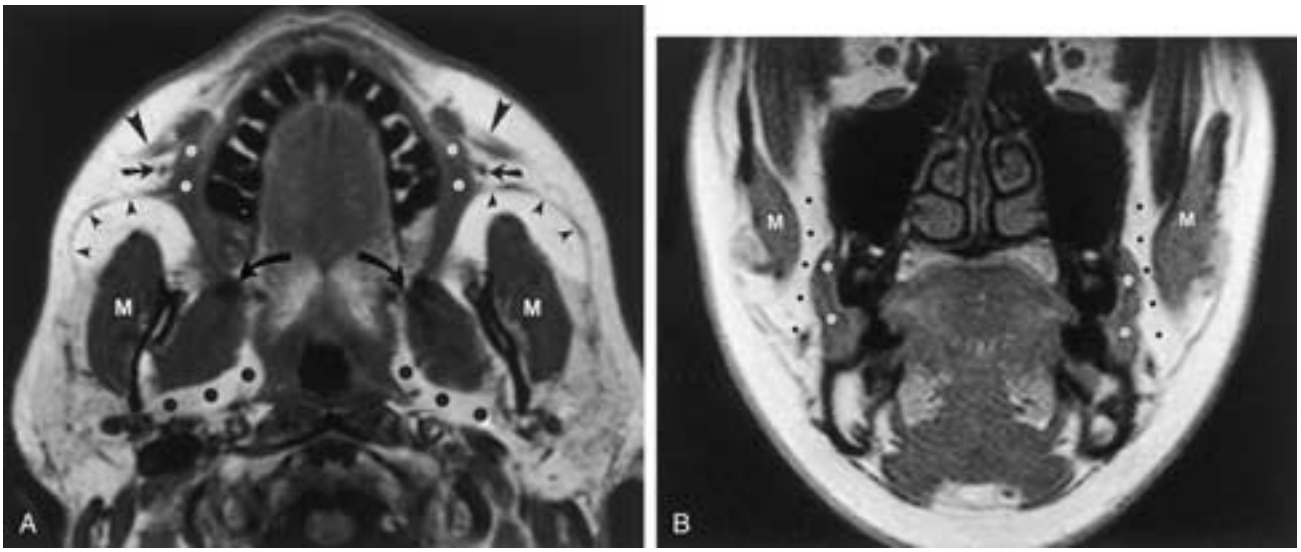
VIEW IMAGE

FIGURE 27-5 Value of the ''puffed cheek'' maneuver. **A**, Axial CT scan with the patient breathing normally. A mass has been identified, but it is difficult to determine if the mass arises from the gingival or buccal mucosa. **B**, Axial CT scan with puffed cheeks places air in the vestibule and confirms that the mass arises from the buccal mucosa. Pathologic examination revealed monomorphic adenoma.

may extend cephalad along this raphe into the upper buccomasseteric region or the suprazygomatic portion of the masticator space, or they may extend caudally to the mylohyoid muscle and along the floor of the mouth. The pterygomandibular raphe also is the anterior boundary of the prestyloid compartment of the parapharyngeal space and the masticator space (see Chapter 38). The lingual and inferior alveolar branches of the trigeminal nerve traverse the parapharyngeal space.

The buccal space, limited by the superior and inferior attachments of the buccinator muscle, is located lateral to the buccinator muscle, deep to the zygomaticus major muscle, and anterior to the mandibular ramus and masseter muscle (Fig. 27-6). It primarily contains the buccal fat pad, the major portion of which lies lateral to the buccinator, with prolongations that may extend between the muscles of mastication.[17] Four projections of fat may be identified extending peripherally from the more central fat pad. Laterally the fat follows the course of the parotid duct posteriorly to lie adjacent to the anterolateral portion of the superficial lobe of the parotid gland. Medially the buccal fat pad extends between the mandible and maxillary sinus and



VIEW IMAGE

FIGURE 27-6 Buccomasseteric region, normal anatomy. (**A**) Axial and (**B**) coronal T1-weighted MR images demonstrate the anatomy of the buccal spaces. These fat-filled spaces lie posterior to the zygomaticus major muscles (*large arrowheads*), anterior and medial to the masseter muscles (*M*), and lateral to the buccinator muscles (*white dots*). The parotid gland ducts are well visualized on the axial image (*small arrowheads*) as they cross the buccal fat pads to pierce the buccinator muscles and open into the vestibule of the mouth opposite the second maxillary molars. The facial veins (*straight arrows* in **A**) are visualized anterior to the parotid ducts, posterior to the zygomaticus major muscles, and lateral to the buccinator muscles. The parapharyngeal space fat (*large black dots* in **A**) is also well seen, medial to the mandible and medial pterygoid muscles and lateral to the pharyngeal constrictor muscles. The region of the pterygomandibular raphe is indicated by the curved arrows in **A**. The buccal space fat is indicated by the small black dots in **B**.

Copyright © 2003, Mosby, Inc. All rights reserved.

frequently communicates with fat in the masticator space. Superiorly the temporal extensions of the buccal fat are divided into deep and superficial portions based upon their relationship to the temporalis muscle. The anterior extension of the fat pad is located superficial to the parotid duct.[18, 19] The main duct of the parotid gland (Stensen's duct) crosses the masseter muscle, courses transversely through the buccal fat pad, pierces the buccinator muscle opposite the second maxillary molar, and drains into the vestibule of the mouth (Fig. 27-6A).

The parotid duct separates the buccal space into fairly equal-sized anterior and posterior compartments. Fat in the posterior compartment reportedly differs from that in the anterior compartment, being composed of a special type of adipose tissue known as *syssarcosis* that may represent the remnants of the succatory fat pad of infants.[20] This specialized adipose tissue aids in muscular motion such as that required for opening and closing the mouth.[20] The CT attenuation of this specialized adipose tissue is reported to be less than that of fat in adjacent spaces, including the fat within the anterior compartment of the buccal space.[21]

Within the buccal space, the angular segment of the facial artery, originating from the external carotid artery, and the buccal artery, originating from the internal maxillary artery, may be identified. The angular artery extends through the buccal space to reach the nasolabial region. The buccal artery courses to the posteromedial portion of the buccal space between the medial border of the masseter muscle and the lateral border of the buccinator muscle. The facial vein is typically identified on cross-sectional images along the lateral margin of the buccinator muscle, anterior to Stenson's duct. It courses through the buccal space from the nasolabial region to the external jugular venous system and averages 3.5 mm in the transverse dimension.[21] Nerves within the buccal space, not routinely identified on cross-sectional images, include the buccal division of the facial nerve, which primarily innervates the buccinator muscle, and the buccal branch of the mandibular nerve, which innervates the mucosa deep to the buccinator muscle and the skin overlying the buccal space.

When involved by tumor or infection, the buccal space may serve as a route of spread between the mouth and the parotid gland.[22] The lack of fascial compartmentalization superiorly, inferiorly, and posteriorly permits spread of pathology (especially infections) both to and from the buccal space.[21] The buccomasseteric region is commonly affected by disease involving the masticator space, a fascially defined region that contains the muscles of mastication, portions of the mandible, the maxillary artery, and branches of the mandibular division of the trigeminal nerve (Fig. 27-7).[23, 24] Pathology of the masticator space most commonly results from dental infections involving the second and third mandibular molars (see Chapter 38).

PATHOLOGY

Congenital Anomalies

Congenital Absence of the Tongue

Extremely rare, approximately 60 cases of congenital absence of the tongue have been reported.[25, 26] Most reported cases have associated limb defects, micrognathia, and oral synechiae.[27] Reports of associated conductive hearing loss also exist, which have prompted some to suggest that audiologic examinations should be performed in all patients with aglossia/hypoglossia syndromes.[26]

Accessory Parotid Tissue

In approximately 20% of the population, accessory parotid tissue is present, usually just anterior to the parotid gland hilum and almost always above the parotid duct in the

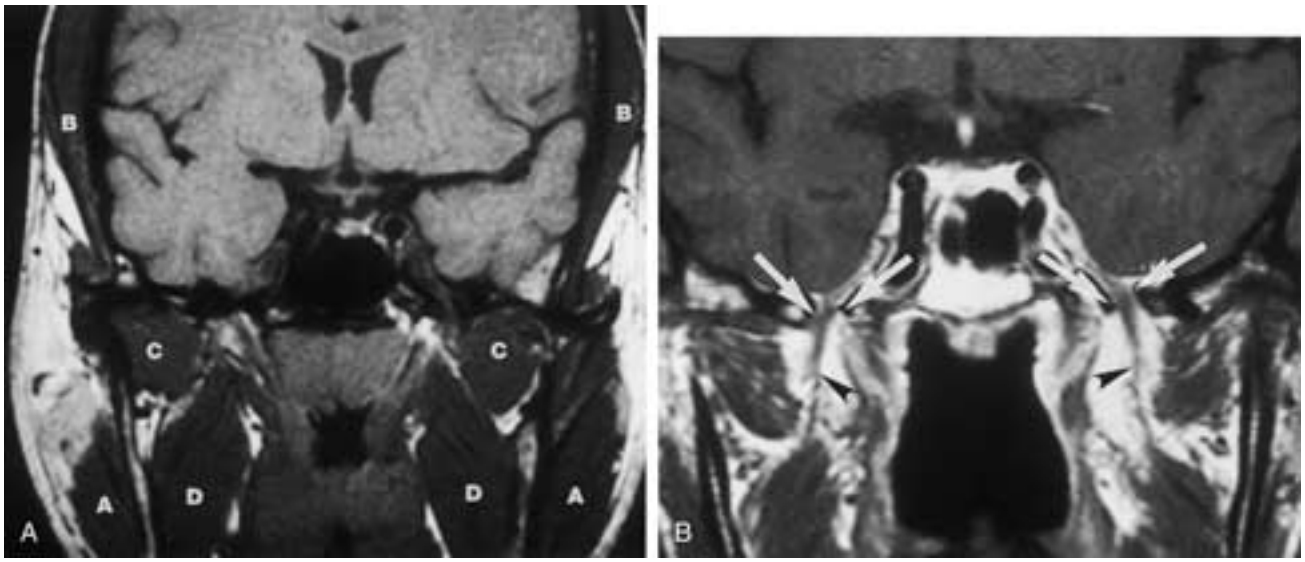


FIGURE 27-7 Masticator space, normal anatomy. **A**, Coronal T1-weighted MR image demonstrates normal muscles of mastication bilaterally. *A*, Masseter muscles; *B*, temporalis muscles; *C*, lateral pterygoid muscles; *D*, medial pterygoid muscles. **B**, Coronal T1-weighted MR image following contrast administration optimally demonstrates the mandibular nerves bilaterally (*arrowheads*) as they traverse the foramen ovale bilaterally (*arrows*).

buccal space, overlying the anterior margin of the masseter muscle (Fig. 27-8). Accessory parotid tissue may be unilateral or bilateral, it drains into Stenson's duct, it is histologically and physiologically identical to tissue in the main parotid gland, and it is affected by the same pathology.[28–30] Accessory parotid tissue is reportedly identified by CT more often than by MR imaging.[21] The topic of pathology affecting parotid tissue is discussed in Chapter 39.

Digastric Muscle Anomalies

Anomalies of the anterior belly of the digastric muscle are uncommon, ranging from interdigitating fibers between the two anterior digastric muscles or between the anterior digastric and mylohyoid muscles to four separate digastric muscle bundles.[31, 32] Both bilateral and unilateral accessory anterior digastric muscles have been described, with a unilateral accessory muscle being more common.[31, 32] Hypoplasia or aplasia of one anterior belly of the digastric muscle has also been reported (Fig. 27-9).[32, 33] The importance of being familiar with various anterior digastric muscle anomalies was highlighted in Larsson and Lufkin's paper, which emphasized the risk of confusing these anomalies with masses in the floor of the mouth or enlarged submental lymph nodes.[31] Hypoplasia or aplasia may also be mistaken for denervation atrophy associated with injury to the mylohyoid nerve; however, the identification of a normal ipsilateral mylohyoid muscle bundle makes a distal V3 injury highly unlikely.[34]

Vascular Lesions

The nomenclature concerning vascular lesions of the head and neck has been a source of confusion, based neither on their cellular kinetics nor on their clinical behavior. Historically, these lesions were named for the size of the channels within the lesions and the type of fluid they contained. In an attempt to address these issues, Mulliken and Glowacki proposed a biological classification for these endothelial malformations based upon their natural history, cellular turnover, histology, and management.[35] Two major types of lesions are recognized: hemangiomas and vascular malformations. Vascular malformations are further subdivided into capillary, venous, arterial, and lymphatic malformations. Although imaging has been used to classify vascular lesions into one of these categories, the more pertinent issue from a treatment standpoint is their classification as either high-flow or low-flow lesions. Malformations with an arterial component are considered high-flow lesions, while those lacking an arterial component are considered low-flow lesions.[36] This topic is discussed further in Chapter 35.

Hemangiomas

Hemangiomas are neoplastic and exhibit increased proliferation and turnover of endothelial cells, mast cells, fibroblasts, and macrophages.[37] They are the most common tumors of the head and neck in infancy and childhood, accounting for 7% to 12% of all benign soft-tissue tumors.[38, 39] Using the classification proposed by Mulliken and Glowacki, the term *hemangioma* should be reserved for those lesions that present in early infancy, enlarge rapidly, and involute by adolescence.[35, 40, 41]

During their proliferative phase, hemangiomas are classified as high-flow lesions that are well circumscribed and angiographically exhibit a lobular pattern of intense persistent tissue staining.[42] The frequent arteriovenous shunting and high flow in these lesions may not permit distinction from high-flow vascular malformations. On MR imaging, the solid component of the hemangioma demonstrates signal intensity isointense or slightly hyperintense to muscle on T1-weighted images and higher signal intensity on progressively more heavily weighted T2-weighted images (Fig. 27-10). Enhancement following contrast administration is typical.[43]

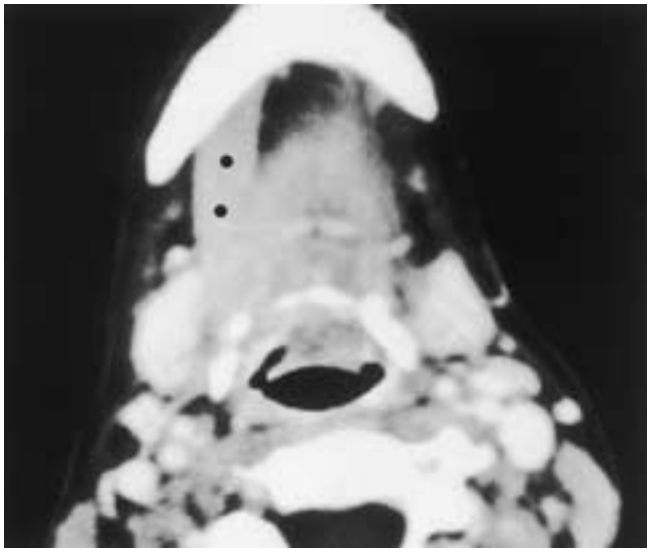

FIGURE 27-9 Digastric muscle aplasia. Axial CT scan demonstrates aplasia of the left anterior belly of the digastric muscle. The right digastric muscle is indicated by the dots.

VIEW IMAGE

FIGURE 27-10 Hemangioma. (**A**) Axial T1-weighted and (**B**) axial T2-weighted MR images. Enlargement of the left masseter muscle without definition of the isointense mass is demonstrated on the T1-weighted MR image in **A**. The hemangioma becomes hyperintense on the T2-weighted image in **B**.

Vascular Malformations

In contrast to hemangiomas, vascular malformations are not tumors, but rather true congenital vascular anomalies that are always present at birth, although they may not manifest clinically until late infancy or early childhood. The proliferation and turnover characteristics of the endothelial cells are normal. These lesions demonstrate slow, steady growth commensurate with the growth of the child, and they neither regress nor involute. Skeletal changes are more commonly associated with vascular malformations (35%) than with hemangiomas.[44] Rapid enlargement of these lesions is reported to occur in association with trauma, infection, or endocrine changes (i.e., in puberty and pregnancy).[45]

Vascular malformations are classified, based upon the predominant type of anomalous vessel involved, into capillary, venous, arterial, and lymphatic malformations.[37, 40] A variety of therapies have been employed for the treatment of vascular malformations and rapidly enlarging hemangiomas, with varying degrees of success. These include steroid administration, laser photocoagulation, sclerotherapy, embolization, subcutaneous interferon, and surgical resection.[46–60]

Capillary Malformations

These lesions were previously referred to as port-wine stains, capillary hemangiomas, and nevus flammeus.[61] They are low-flow lesions and may be associated with the distribution of the trigeminal nerve as one component of the Sturge-Weber syndrome, which also involves an underlying vascular anomaly of the choroid plexus and leptomeninges. The underlying cheek, lip, and gingiva may be affected, and gingival hypertrophy or chronic hemorrhage may be associated with these capillary malformations.

Venous Malformations

These lesions, occasionally termed *cavernous hemangiomas*, unlike true hemangiomas, may involve bone and do not involute.[61] They are the most common ones to affect the oral cavity and share many imaging features with subcutaneous hemangiomas. Venous malformations may attain enormous size and cause airway compromise when located in the extracranial head and neck, and although they are predominantly soft-tissue masses, they may infiltrate deeply along fascial planes and rarely may be entirely intramuscular.[62, 63] Of all the skeletal muscle hemangiomas-venous malformations, approximately 14% occur in the head and neck region, with the masseter muscle being most commonly affected, followed by the trapezius and sternocleidomastoid muscles.[64, 65] These lesions typically present as muscle-density masses on CT and manifest variable patterns of enhancement.[22] Like their capillary counterparts, venous malformations are low-flow lesions supplied by small arteries. On CT they may not demonstrate sufficient enhancement to enable separation of their margins from surrounding muscles, while angiographically one may not be able to identify their arterial supply.[66] On MR imaging, these lesions may appear very similar to deep hemangiomas because they are isointense or hyperintense to muscle on T1-weighted images, hyperintense on T2-weighted images, and typically enhance following the administration of contrast (Fig. 27-11). The identification of discrete areas of homogeneous high signal intensity, representing venous lakes, or the presence of phleboliths may be extremely helpful in suggesting the diagnosis of a venous malformation (Fig. 27-12).[39, 66, 67] Venous malformations are encountered in the blue rubber bleb nevus syndrome and are also associated with multiple enchondromas in Maffucci's syndrome.[68]

Arterial Malformations

These lesions are high-flow malformations that result from abnormal blood vessel morphogenesis. Arteriovenous malformations and fistulae are included in this category (Fig. 27-13). The head and neck region is considered one of

Copyright © 2003, Mosby, Inc. All rights reserved.

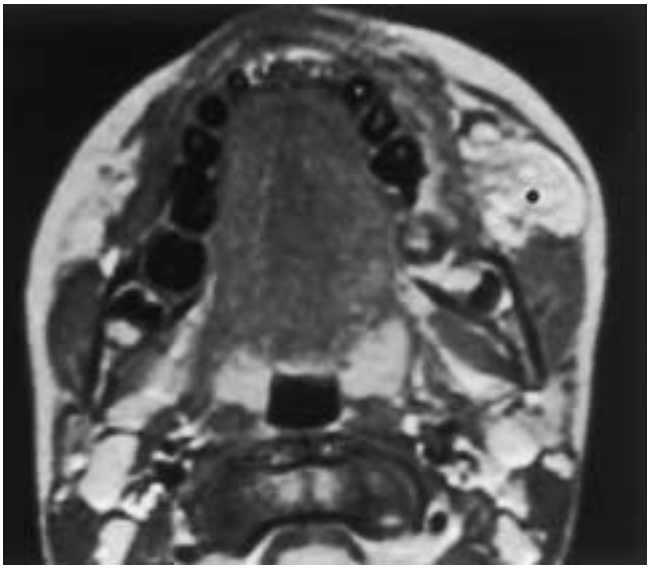
the more common sites for congenital arterial malformations, although they are uncommonly encountered within the oral cavity proper.[1] Angiographically, arterial malformations are characterized by rapid flow and enlarged, tortuous arteries and draining veins. Parenchymal staining is unusual. On MR imaging, the enlarged arterial components appear as flow voids on T1-weighted and T2-weighted images.

A subgroup of patients demonstrates combined vascular malformations that share features of both high-flow and low-flow lesions.[41] Capillary-venous, veno-lymphatic, and arteriovenous malformations have all been described. These lesions may be highly invasive, become enormous in size, and may be resistant to all forms of therapy, tending to involve the deep musculature and subcutaneous tissues.[40] On MR imaging these lesions demonstrate serpiginous flow voids, characteristic of an arterial malformation, as well as a soft-tissue infiltrating component typical of a venous malformation (Fig. 27-14).[40]

Lymphatic Malformations (Lymphangiomas)

Although the vast majority of lymphatic malformations are congenital in origin, some acquired lesions, presenting later in life, have been reported in association with tumors, trauma, infection, or previous surgical procedures (iatrogenic).[69, 70] Lymphatic malformations are classified, based on their clinical and histologic characteristics, into four categories: (1) capillary lymphangiomas, (2) cavernous lymphangiomas, (3) cystic lymphangiomas (hygromas), and (4) lymphangioma-hemangiomas.[69, 71] This topic is discussed further in Chapter 35.

Capillary lymphangiomas are cutaneous lesions that commonly affect the oral region, appearing as small, wart-like excrescences on the skin or mucous membranes. The simplex variety is confined to the epidermis and superficial dermis, although the circumscriptum variety can extend into deeper layers of the dermis.[69, 71]



VIEW IMAGE

FIGURE 27-11 Venous malformation. Proton density MR image demonstrates a discrete, mildly heterogeneous, high signal intensity mass (*dot*) within the left buccal space immediately anterior to the left masseter muscle.

Cavernous lymphangiomas affect the subcutaneous tissues and may extend deeply into underlying muscles. They are usually diagnosed within the first months of life and commonly affect the oral cavity, neck, and tongue.[69, 71] These lesions may be subclassified into loose and compact forms. The loose variety is most often encountered in the mucous membranes of the lips, cheeks, and floor of the mouth, and the compact form more commonly affects the tongue, where the surrounding structures are more muscular.[69] There are isolated reports of lymphangiomas, probably of the cavernous variety, involving the masseter muscle.[72] Diffuse lymphangiomas of the tongue are usually bilateral (Fig. 27-15), may produce macroglossia, and lead to a variety of dentoalveolar complications, although respiratory problems seem to be rare.[73]

Cystic lymphangiomas (hygromas) are the lesions that most often present for imaging. The vast majority of these lesions are encountered in the cervical region, with a predilection for the left posterior neck.[69] When they extend to involve the floor of the mouth, sublingual and submandibular regions, or the tongue, cystic hygromas may displace the soft tissues sufficiently posteriorly into the oropharynx to obstruct both breathing and swallowing.[69] Although these lesions tend to enlarge slowly, they may suddenly increase in size secondary to trauma or hemorrhage or in association with a viral infection when large quantities of lymphatic fluid are produced from lymphoid follicles in the cyst wall.[74]

On imaging studies, cystic hygromas appear as large, single, or multiseptated, heterogeneous fluid-filled masses. They are of low density on CT, are usually poorly circumscribed, and demonstrate variable enhancement of the septations following contrast administration (Fig. 27-16).[75] At times it may be difficult to separate these lesions from surrounding soft-tissue structures of similar attenuation on CT examinations.[76] Multiple fluid-fluid levels may occur in the presence of hemorrhage.[77] On MR imaging, cystic hygromas typically manifest a signal intensity that is hypointense or isointense to muscle on T1-weighted images and a high signal intensity, greater than that of fat, on T2-weighted images (Fig. 27-17).[76, 78] Occasionally, T1-weighted hyperintensity may be present in association with clotted blood, and most cystic hygromas have a signal intensity greater than that of CSF on both T1-weighted and T2-weighted sequences, suggesting the presence of proteinaceous fluid that may contain subacute blood or lipid components.[78, 79] Focal inhomogeneities, corresponding to fibrous septae, are identified in many patients (Fig. 27-18). Contrast-enhanced MR imaging usually demonstrates enhancement of the cyst wall and septae, providing clearer definition of the capsule and septae than do the noncontrast images.[78]

Lymphangioma–hemangiomas (diffuse systemic lymphangiomas) are rare and not well described in discussions of lymphatic malformations.[69] They have not been reported in the oral cavity.

Dermoid Cysts

Dermoid cysts are the least common of the congenital neck lesions, accounting for only 7% of all cysts in this location.[80] Despite Meyer's detailed classification of these lesions into epidermoid, dermoid, and teratoid forms, the term *dermoid cyst* is commonly used in reference to all three types of lesions without regard to their differing histolo-

VIEW IMAGE

gies.[81] This topic is discussed further in Chapter 35. A histologic distinction should be made between epidermoid cysts and dermoid/teratoid cysts because the latter two cysts have malignant potential, whereas epidermoid cysts do not.[82]

The most popular theory regarding the etiology of these lesions suggests that they are derived from epithelial rests that become enclaved during midline closure of the first (mandibular) and second (hyoid) branchial arches.[83] This theory may help to explain the simultaneous occurrence of sublingual and submental cysts. A case of a dermoid cyst of the floor of the mouth and a coexisting gastric choristoma has also been reported.[84]

When they occur in the oral cavity, dermoid cysts most

Copyright © 2003, Mosby, Inc. All rights reserved.

commonly involve the floor of the mouth (sublingual, submental, or submandibular regions), although other sites also have been reported including the lips, tongue, and buccal mucosa.[83, 85–90] The sublingual location is reported to be the most common (52%), followed by the submental (26%) and submandibular (6%) regions. The remaining 16% involve more than one location.[82] Extracapsular excision of oral cavity cysts is performed by either an intraoral or an external approach, depending upon the relationship of the cyst to the mylohyoid muscle.[82, 91] For those cysts that lie above the mylohyoid muscle (sublingual), an intraoral approach is preferable because it avoids a conspicuous scar, preserves the mylohyoid muscle, and is associated with a shorter recovery time. Those lesions that lie inferior to the mylohyoid muscle (submental and submandibular cysts) must usually be removed via an external approach. Therefore, imaging localization of the cyst in relation to the mylohyoid muscle is extremely helpful for appropriate surgical planning. Sagittal and especially coronal imaging are useful in this regard.[91] These lesions can occur either in the midline or just off the midline.

On CT, simple (epidermoid) dermoid cysts typically appear as low-density, well-circumscribed, thin-walled, unilocular masses that are less dense than muscle (Fig.

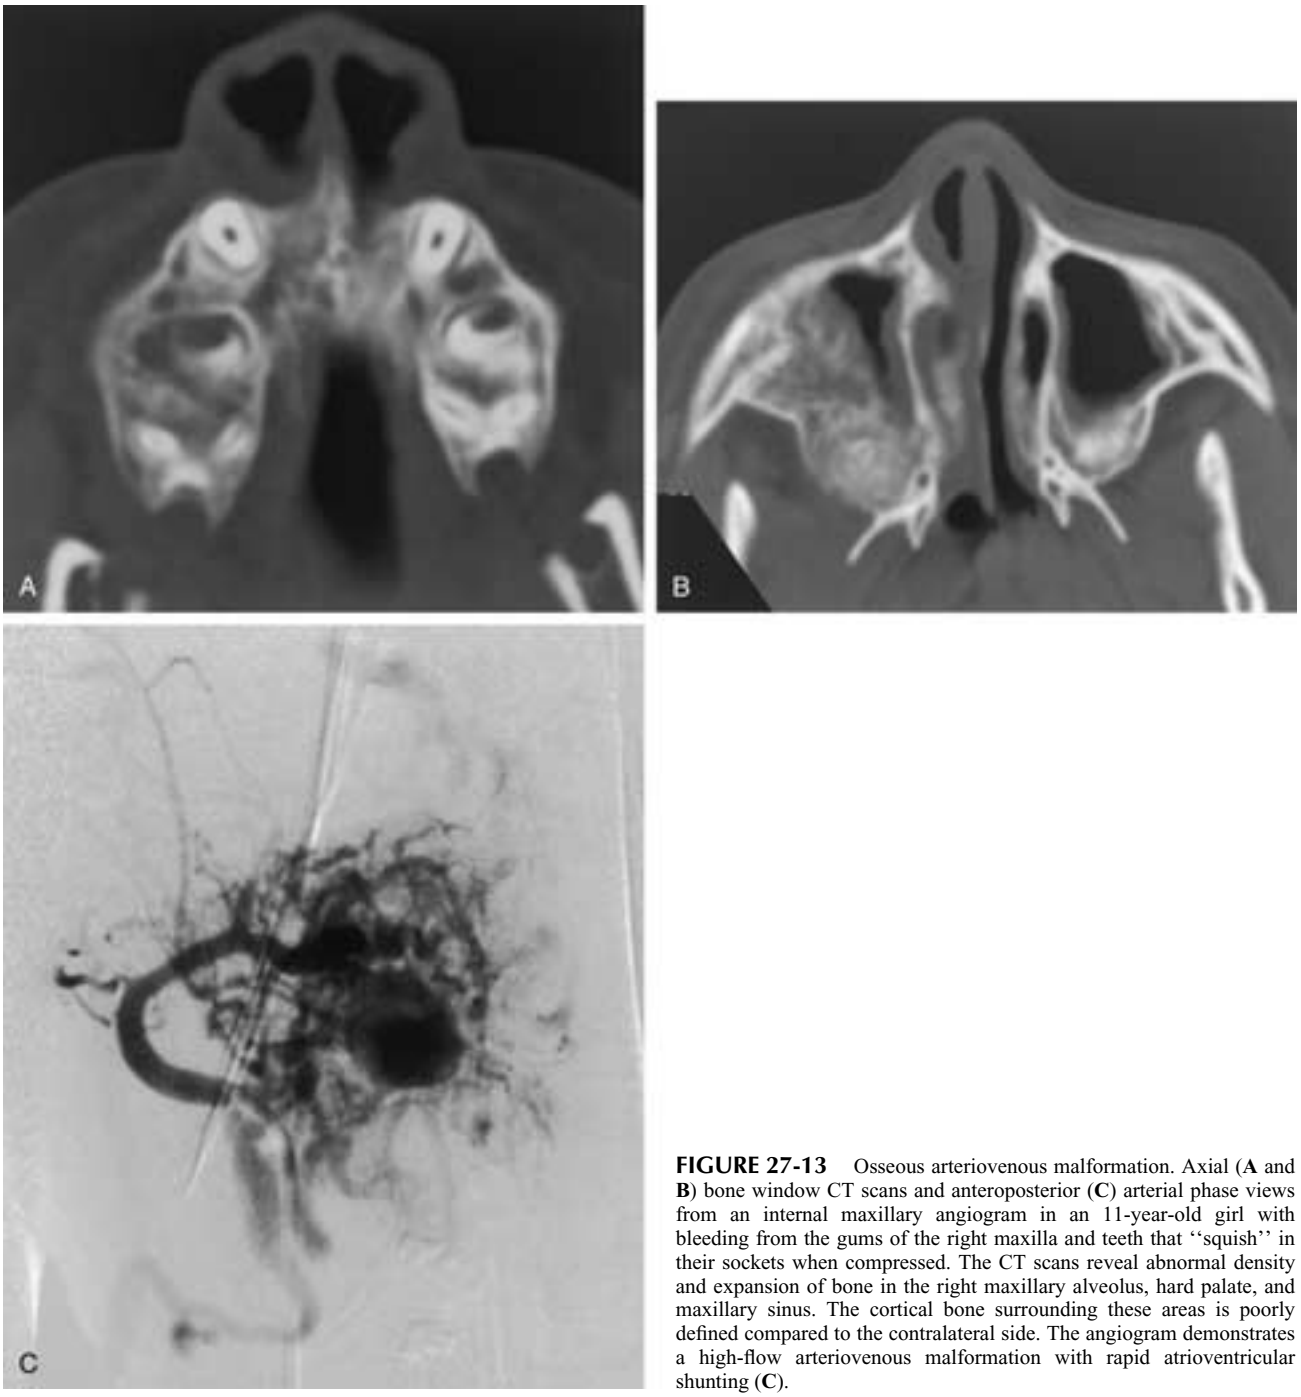

FIGURE 27-13 Osseous arteriovenous malformation. Axial (**A** and **B**) bone window CT scans and anteroposterior (**C**) arterial phase views from an internal maxillary angiogram in an 11-year-old girl with bleeding from the gums of the right maxilla and teeth that ''squish'' in their sockets when compressed. The CT scans reveal abnormal density and expansion of bone in the right maxillary alveolus, hard palate, and maxillary sinus. The cortical bone surrounding these areas is poorly defined compared to the contralateral side. The angiogram demonstrates a high-flow arteriovenous malformation with rapid atrioventricular shunting (**C**).

27-19). The wall of the cyst usually enhances following contrast administration, and in the absence of fat globules, epidermoid and dermoid cysts are indistinguishable.[92] On MR imaging, epidermoid cysts are of low signal intensity on T1-weighted images and of high signal intensity on T2-weighted images, reflecting their fluid content. When located within the sublingual space, these lesions may be impossible to distinguish from other cystic lesions, such as a simple ranula, on the basis of imaging criteria alone.

Compound dermoid cysts have a more variable appearance, depending upon their fat content. On CT they may appear filled with homogeneous low-attenuation (0 to 18 HU) material or the central cavity may demonstrate a fat-fluid level or a single fat globule (Figs. 27-20 and 27-21). The identification of multiple discernible low-attenuation

nodules, due to coalescence of fat globules within the fluid matrix, has a ''sack-of-marbles'' appearance and is virtually pathognomonic for a compound dermoid cyst in this location (Fig. 27-22).[79] On MR studies, compound dermoid cysts may be either isointense or hyperintense to muscle on T1-weighted images, depending upon their lipid content (Figs. 27-23 and 27-24).[91] They are typically hyperintense on T2-weighted sequences, and the use of contrast permits determination of the thickness of the cyst wall, typically 2 to 6 mm.[91]

Thyroglossal Duct Cysts

Thyroglossal duct cysts (TGDCs) are the most common nonodontogenic cysts occurring in the neck, and they account for 70% of congenital neck abnormalities.[1, 93] This

FIGURE 27-23 Dermoid cyst. Axial T1-weighted MR image reveals the lesion to be of high signal intensity but of slightly less intensity than that of the subcutaneous fat. The relationship of this lesion to the right mylohyoid muscle (*white dot*) is clearly established. The fatty lingual septum is displaced slightly to the left of midline. This lesion involves much of the right sublingual space, dissecting posteriorly to involve the deep aspect of the right submandibular space.

27-25 and 27-26). If any portion of the thyroglossal duct persists, secretions from the epithelial lining (likely secondary to repeated local trauma or inflammation) may give rise to a TGDC. One diagnostic pearl for the clinical identification of these lesions is their upward movement when the tongue is protruded, a reflection of the duct origin at the foramen cecum.[79] Approximately 65% of TGDCs are infrahyoid in location, in the region of the thyrohyoid membrane, 15% are at the level of the hyoid bone, and the remaining 20% are suprahyoid.[1] In contrast to the typically paramedian infrahyoid TGDC, suprahyoid TGDCs are commonly midline, located between the bellies of the anterior digastric muscles (Fig. 27-25). They are frequently embedded within or lie below the mylohyoid sling in the submental region, and rarely they may present as masses within the floor of the mouth.[94] From 1% to 2% of TGDCs are reported to be intralingual.[95]

On CT, TGDCs are usually thin-walled, well-circumscribed, unilocular cystic lesions, 2 to 4 cm in diameter, that exhibit capsular enhancement (Fig. 27-25).[96] Occasionally, a TGDC may be septated, and this should be viewed with some caution. Figure 27-27 demonstrates what appears to be a simple septated TGDC just below the level of the hyoid bone on CT. However, MR imaging reveals differing signal intensities in the two compartments, with a solid tumor in the posterior compartment that proved to be papillary carcinoma.

On MR imaging, TGDCs exhibit low to intermediate signal intensity on T1-weighted images, depending on the protein content of the cyst, and are of high signal intensity on T2-weighted images. The adjacent soft tissues and fascial planes are normal unless infection, which is reported in approximately 60% of patients, is present.[97] In the presence of infection, thickening of the overlying skin and/or platysma muscle and induration of subcutaneous fat may be demonstrated, making it extremely difficult to differentiate the infected TGDC from malignant submental adenopathy.[96] In this regard, close attention to the appearance of the cyst wall and clinical information may be very helpful (Fig. 27-28).

Less than 1% of thyroglossal duct abnormalities are associated with coexisting carcinoma, papillary carcinoma being the most common (80%). Approximately 95% of TGD carcinomas are thyrogenic and 5% are squamous in nature, appearing more aggressive and occurring in an older age group.[98] Virtually every type of thyroid malignancy has been reported in association with these cysts, which arise from ectopic rests of thyroid tissue within the duct walls, not from the duct itself. Only medullary carcinoma has not been reported within a TGDC, as these carcinomas are unique in that they develop from the ultimobranchial bodies and not from the thyroid anlage.[99–104] Most of these thyroid carcinomas are rarely suspected preoperatively.[105]

Lingual Thyroid

Failure of the thyroid gland to descend from the foramen cecum to the lower neck results in residual thyroid tissue along the thyroglossal duct tract. In autopsy studies, ectopic thyroid tissue less than 3 mm in size has been reported in 10% of the normal population.[1] Ectopic thyroid tissue, which may or may not be functioning, has a high female/male ratio (7:1), which is attributed to hormonal disturbances in females during puberty and pregnancy.[106] The tongue is the most common location, accounting for 90% of ectopic thyroid tissue, most of which occurs in the midline dorsum of the tongue, although rare cases of involvement of the entire tongue have been reported.[107, 108] Ectopic thyroid tissue is typically asymptomatic and is discovered incidentally; however, symptoms of dysphagia, dysphonia, stridor, dyspnea, hemorrhage, and hoarseness may occur.[109–112] Hypothyroidism and cretinism have both been reported in patients with lingual thyroid tissue.[113, 114] Malignancy in lingual thyroid tissue is rare.[115] In a large percentage of patients (70% to 80%), no other functioning thyroid tissue is present, and surgical excision would render the patient permanently hypothyroid. For this reason, if surgery is contemplated, iodine-123 radionuclide scanning should be performed to establish the presence or absence or normal functioning thyroid tissue within the neck. This study will also serve to establish the presence of functioning lingual thyroid tissue.

On noncontrast CT, lingual thyroid tissue usually presents as a hyperdense mass within the intrinsic musculature of the tongue and enhances avidly, typically in a homogeneous fashion (Fig. 27-29).[3, 112] Markedly heterogeneous contrast enhancement has been reported in a patient with goitrous changes and thyroiditis affecting the lingual thyroid tissue.[111] On MR imaging, lingual thyroid tissue is isointense or hyperintense to the tongue musculature on both T1-weighted and T2-weighted sequences and strongly enhances following contrast administration.[110] The imaging characteristics of pathologic lingual thyroid tissue are similar to those of pathology involving the thyroid gland (multinodular goiter, thyroiditis, carcinoma, etc.) (Fig. 27-30).

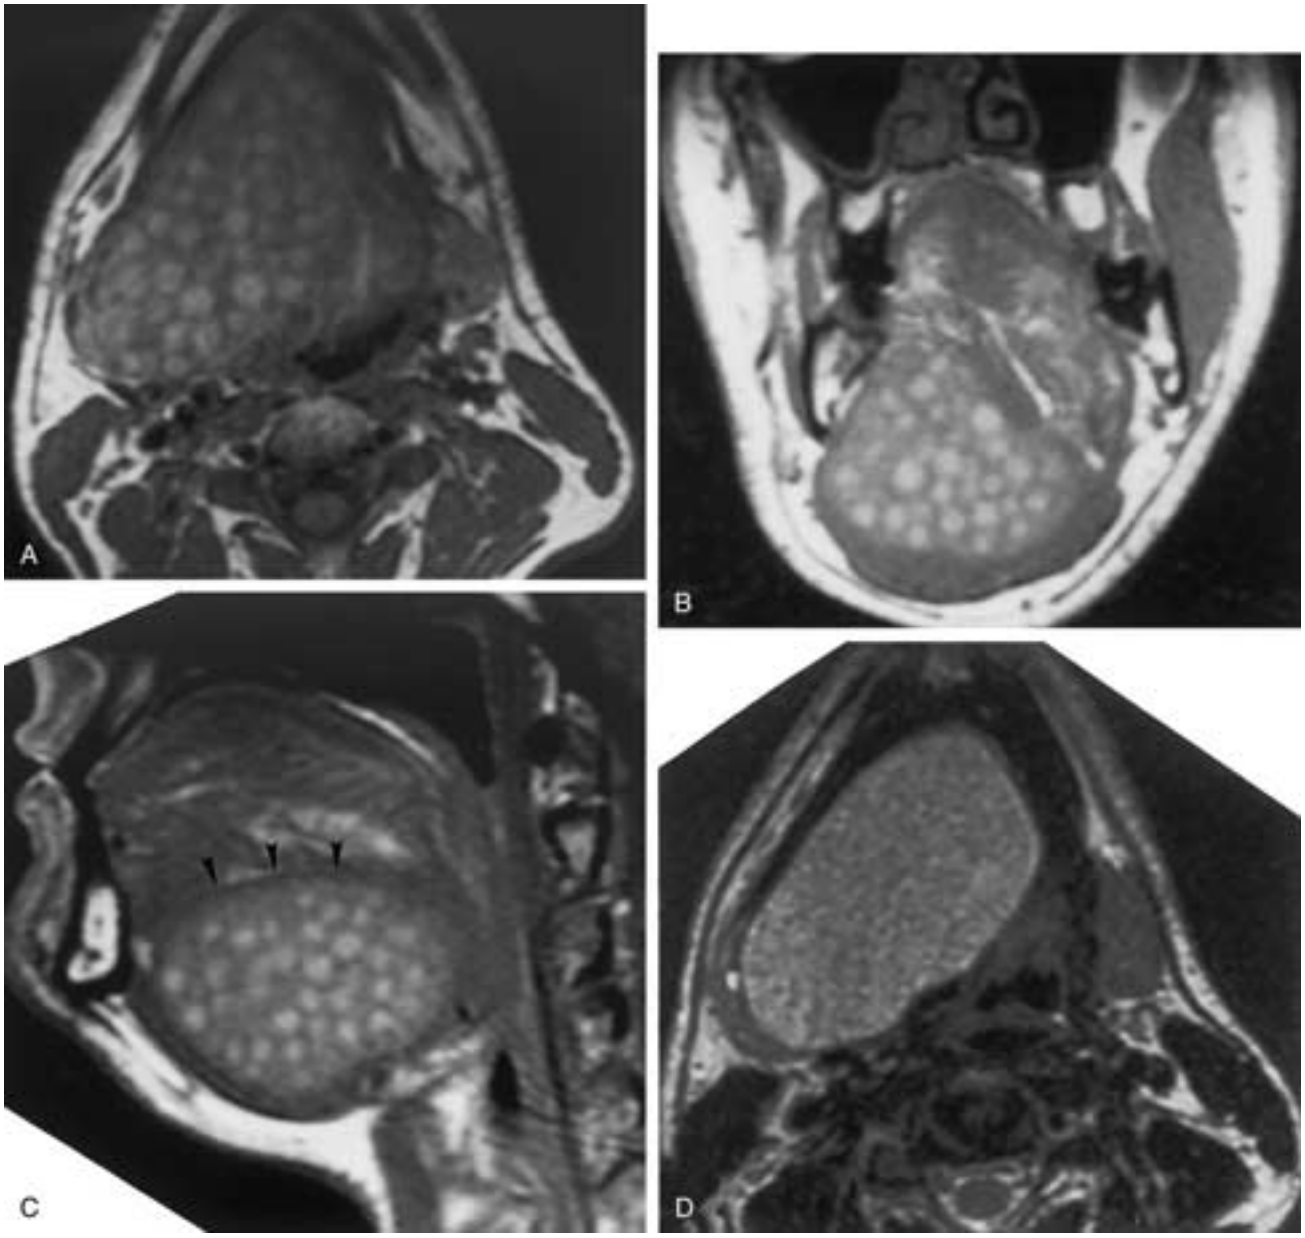
Lingual Artery Aneurysms

Aneurysms of the external carotid artery branches are distinctly uncommon, with the superficial temporal artery being most often affected as a result of trauma.[116] Aneurysms of the lingual artery, on the other hand, are uncommon.[117–120] Rare reports of presumed congenital lingual artery aneurysms (absence of previous trauma) exist.[118] In one report, a patient with bilateral lingual artery aneurysms presented with ecchymosis of the neck following spontaneous rupture of one of the aneurysms.[120] Batten and Heeneman reported a case of a 2 × 3 cm traumatic facial artery (mandibular branch) aneurysm presenting as a pulsatile mass in the submental region following uncomplicated mandibular alveoplasty.[121] CT may suggest the diagnosis but may not be able to distinguish an aneurysm from other vascular lesions, and the aneurysm's appearance is variable, depending upon the degree of thrombosis (Fig. 27-31).[120] Although the use of MR imaging has not been reported, its ability to demonstrate vascular structures as flow voids may prove useful in the evaluation of these lesions, as might MR angiography.



VIEW IMAGE

FIGURE 27-24 Dermoid cyst. T1-weighted MR images in the axial (**A**), coronal (**B**), and sagittal (**C**) planes demonstrate a large sublingual dermoid cyst characterized by multiple fat globules, which are easily identified by their high signal intensity. The relationship of this lesion to the floor of the mouth musculature is well demonstrated on the sagittal image (**C**), on which it lies between the fibers of the mylohyoid muscle inferiorly and those of the geniohyoid muscle (*arrowheads*) superiorly. Axial T2-weighted MR image (**D**) reveals a very heterogeneous signal to the contents of this dermoid cyst, without definition of the individual fat globules so easily visualized on the T1-weighted images. Heterotopic Tissues of the Tongue

Rare reports of heterotopic central nervous system tissue involving the dorsum of the tongue exist in the literature.[122, 123] Bras et al. suggested that glial tissue in the tongue may occur by dislocation of neuroectodermal cells that accompany migrating muscle-forming cells into the tongue.[124] In the few reported cases, newborns, young infants, and females were more often affected.

Approximately 30 cases of heterotopic intralingual cysts of foregut origin have been described in the oral cavity, 97% involving the tongue and floor of the mouth. The nomenclature regarding these cysts is confusing, and these lesions

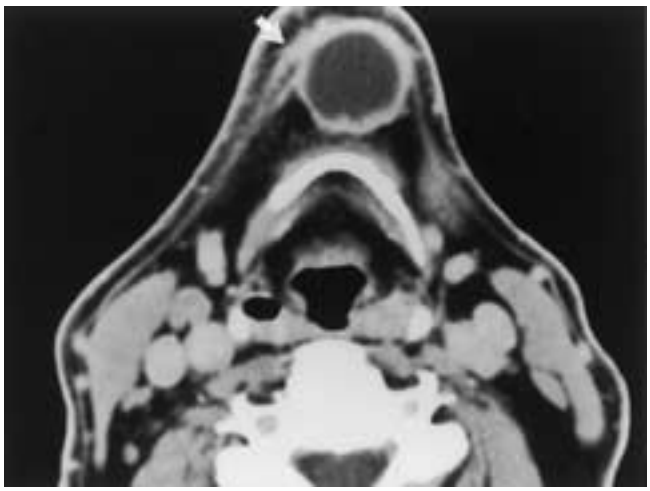
have been variously termed *mucus cysts*,[125] *glossoceles*,[126] *retention cysts of the tongue*,[127] *lingual cysts*,[128] *median lingual cysts*,[129] *gastrointestinal mucosal cysts*,[130] and *choristomas*.[131, 132] In 1982, Constantinides et al. suggested that any cyst containing ciliated epithelium, with or without other types of epithelia, should be regarded as a cyst of foregut origin because ciliated epithelium was considered the hallmark of the primitive foregut.[133] The occurrence of these lesions is probably related to entrapment of undifferentiated, noncommitted endoderm at the junction of the oral tongue, originating from portions of the second and third branchial arches, during the third to fourth weeks of fetal life. These cysts typically occur in infants and young children, and approximately 80% of affected individuals are male (Fig. 27-32). Most cysts are 1 to 3 cm in size, although a 9 cm cyst has been reported. Thirty percent of affected infants may have symptoms related to difficulty with feeding, swallowing, and breathing. The CT appearance of a single lesion is described as ''a relatively well defined cystic structure without loculation or septation.''[134]



VIEW IMAGE

FIGURE 27-28 Malignant submental adenopathy in a 63-year-old male with a history of squamous cell carcinoma of the left external auditory canal 7 years earlier. The enhancing margin, however, has irregular thickness and is ''stranded'' (*arrow*), the overlying fat is ''dirty'' in appearance, and the skin is thickened. Contrast this appearance with that of the thyroglossal duct cyst in Figure 27-25.

Infections and Inflammatory Lesions

Abscess, Cellulitis, and Sialoliths

Infections within the oral cavity, including the sublingual and submandibular regions, most commonly result from either stenosis or calculi within the salivary gland ductal systems or from dental infections or manipulation. In many cases, infections may primarily involve the masticator space and secondarily spread to involve the oral cavity. The relationship of the apices of the mandibular teeth to the mylohyoid ridge may determine which region is primarily involved by dental infections. The roots of the second and third molars lie below the mylohyoid ridge, and apical infections of these teeth directly involve the submandibular space. By comparison, the apices of the first molar and premolar roots are located above the mylohyoid ridge, and infections of these teeth preferentially involve the sublingual region.[135]

For evaluation of oral cavity infections in adults, CT with contrast enhancement is preferred to MR imaging because CT is superior for demonstrating small calculi and is usually superior for assessing the integrity of the mandibular cortex

and evaluating for associated osteomyelitis. In addition, total examination times are typically shorter, an important consideration for the acutely ill patient.[136] For patients in the pediatric age group and for adults in whom the use of iodinated contrast is contraindicated, MR imaging may be a preferable modality. The ability of MR to image in multiple planes and the decreased susceptibility to artifacts from dental amalgams are distinct advantages over CT. Every effort must be made to identify associated osteomyelitis in these patients to ensure that appropriate long-term antibiotic treatment is provided. If dental amalgams prevent this assessment, nuclear scintigraphy or MR imaging should be performed.

On CT, an abscess appears as a single or multiloculated low-density area, with or without gas collections, that usually conforms to fascial spaces and demonstrates peripheral rim enhancement (Figs. 27-33 to 27-36). On MR imaging, an abscess typically has low T1-weighted and high T2-weighted signal intensities. Rim enhancement following contrast administration is identified in mature abscesses (Fig. 27-37). In addition to the abscess cavity, cutaneous and subcutaneous manifestations of infection are typically present, including myositis (adjacent muscle enlargement), thickening of the overlying skin, ''dirty'' edematous fat, and enhancement of fascial planes (Figs. 27-38 to 27-40). These cutaneous manifestations are not as obvious on MR imaging as they are on CT, which is one limitation of MR imaging when scanning for infections.[136] The presence of these cutaneous and subcutaneous manifestations, without a definite low-density collection, is consistent with cellulitis.

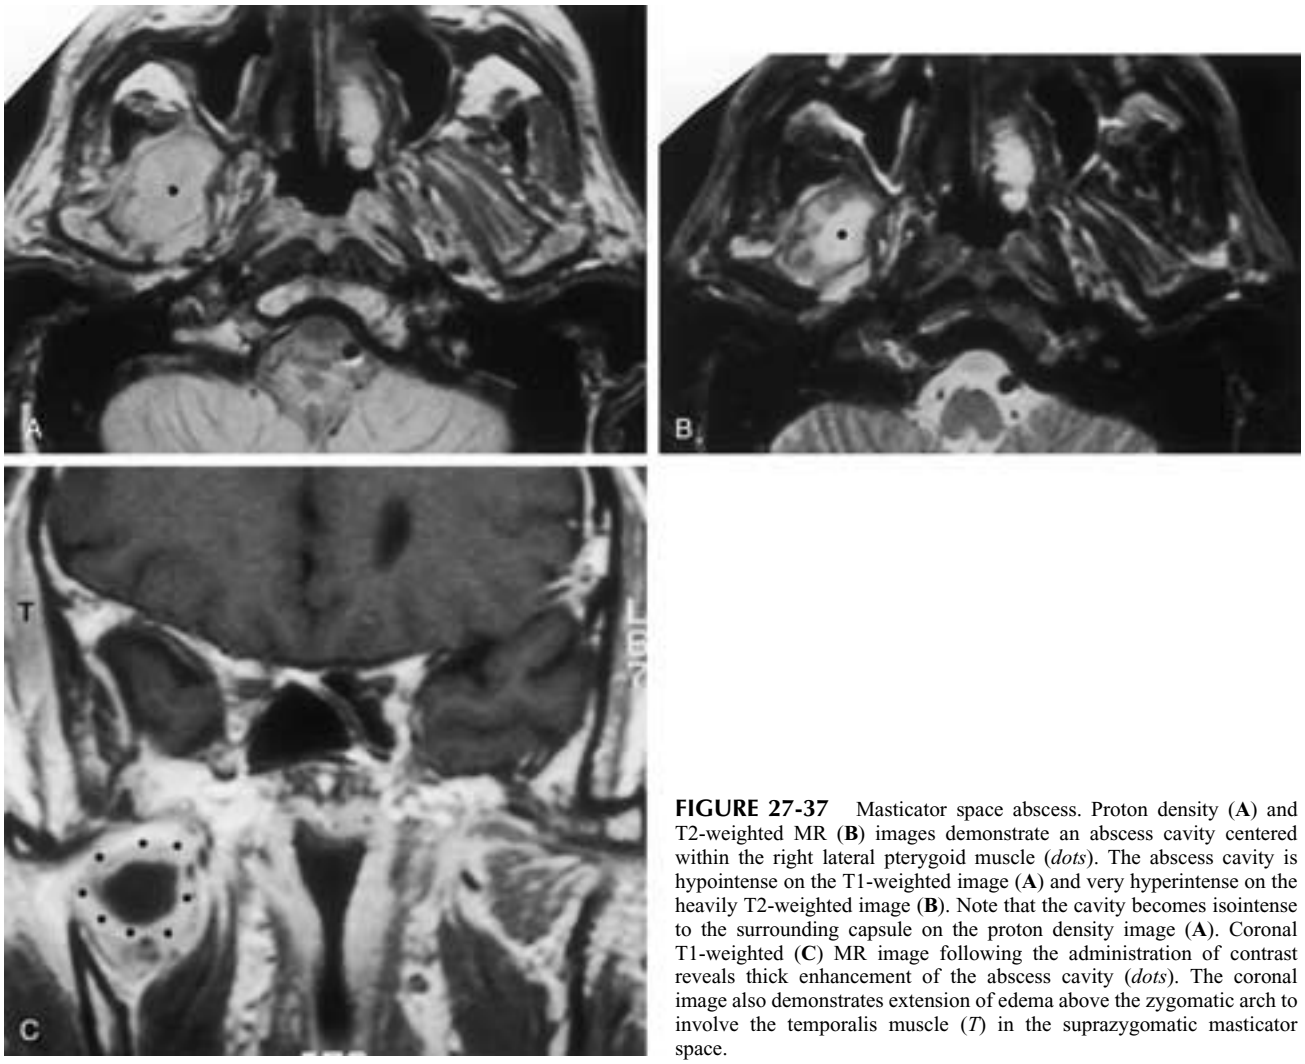
FIGURE 27-36 Periapical abscess in a 16-year-old male with tooth pain and left facial swelling. Contrast-enhanced axial CT scan shows an abscess cavity within the mandible in the region of the first molar. Rim-enhancing abscesses also involve both the buccal and lingual gingiva (*arrows*).

Primary abscesses of the tongue are rare.[137, 138] Most lingual abscesses originate via direct invasion from trauma (i.e., jagged teeth, bite injury, foreign body penetration) or local infection (apical infections from molar teeth, infected lingual tonsils or TGDCs). The imaging features of tongue abscesses are similar to those of nonlingual lesions.

Inflammatory processes involving the submandibular gland most often result from obstructing intraductal calculi. The inflamed gland is enlarged and painful, and purulent material may be expressed from the duct in most bacterial infections. Salivary pathology is discussed further in Chapter 39.

Obstruction of Wharton's duct by stricture or a calculus may lead to proximal dilation of the duct and, if protracted, may result in submandibular sialadenitis or gland abscess (Figs. 27-41 and 27-42). When sialolithiasis is suspected, the examination of choice is a nonenhanced CT scan (Fig. 27-43). Reconstructed images may be useful in the detection of multiple sialoliths.[139] Contrast should not be used initially because blood vessels in this region may simulate small sialoliths (if infection is suspected, a contrast-enhanced scan may be obtained following the nonenhanced study). Visualization of submandibular gland ducts is common on both CT and MR imaging. However, a duct more than 3 mm



VIEW IMAGE

FIGURE 27-37 Masticator space abscess. Proton density (**A**) and T2-weighted MR (**B**) images demonstrate an abscess cavity centered within the right lateral pterygoid muscle (*dots*). The abscess cavity is hypointense on the T1-weighted image (**A**) and very hyperintense on the heavily T2-weighted image (**B**). Note that the cavity becomes isointense to the surrounding capsule on the proton density image (**A**). Coronal T1-weighted (**C**) MR image following the administration of contrast reveals thick enhancement of the abscess cavity (*dots*). The coronal image also demonstrates extension of edema above the zygomatic arch to involve the temporalis muscle (*T*) in the suprazygomatic masticator space.

FIGURE 27-38 Abscess or cellulitis. Axial contrast-enhanced CT scan demonstrates a small abscess cavity (*arrow*) at the posterior aspect of the right tongue, between the mylohyoid (*M*) and hyoglossus (*H*) muscles, both of which are enlarged due to associated myositis. Small collections of gas can be seen to dissect between the muscle fibers. Marked cellulitis involving multiple fascial spaces is identified. The right platysma muscle (*black dots*) is markedly thickened, and the left muscle is much less affected. There is marked edema and a ''dirty'' appearance of the subcutaneous fat involving the right side of the face. The skin overlying this edematous fat is slightly thickened as well. This edema and cutaneous thickening extend posteriorly in the superficial space to at least the margin of the right trapezius muscle (*T*).

VIEW IMAGE

FIGURE 27-39 Abscess or cellulitis. Axial contrast-enhanced CT scan demonstrates a large, heterogeneous, multiloculated abscess involving the left submandibular space. Associated with this abscess is marked thickening of the overlying skin (*white arrows*), thickening of the left platysma muscle (*black dots*), and a ''dirty'' stranded appearance to the subcutaneous fat. Note that there is significantly more cellulitis associated with this abscess than with the abscess illustrated in Figure 27-34.

in diameter, whether intraglandular or extraglandular, indicates possible obstruction, and there should be a thorough evaluation to exclude calculi or obstructing floor-of-mouth tumors (Figs. 27-44 and 27-45).[140] This holds true for the parotid gland and Stenson's duct as well (Fig. 27-46). When large, calculi may be visualized on MR imaging as well as CT (Fig. 27-47), but MR imaging should be reserved for patients with demonstrated sialoliths in whom glandular parenchymal changes require assessment or for patients in whom a sialolith is not demonstrated by CT.[141, 142] MR sialography has recently become possible and is reported to be superior to ultrasound for the detection of sialoliths, but it is currently less sensitive than CT (Fig. 27-48).[141, 143–145]

Ludwig's Angina

Ludwig's angina is a term used to refer to an extensive infection of the floor of the mouth, typically caused by oral

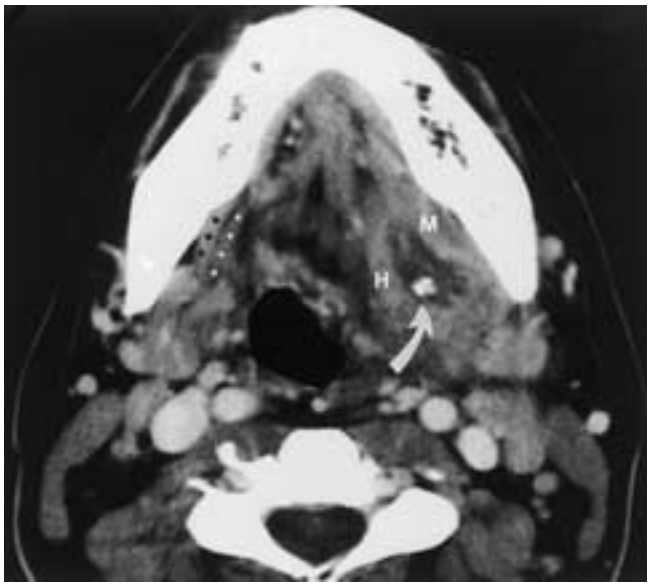
The most superior extent of the resulting abscess involving the left submandibular gland may be identified on this image (*arrowheads*). **B**, Axial CT scan with contrast enhancement at a lower level reveals a normal right submandibular gland (*S*). An extensive abscess involves the majority of the left submandibular gland (*arrowheads*).

flora (especially streptococcal and staphylococcal bacteria). Specifically, infections of the mandibular molars account for up to 90% of reported cases.[146] Before the antibiotic era, infections in this region dissected inferiorly along fascial planes into the mediastinum, and the patient presented with angina-like chest pain. As early as 1939, Grodinsky established strict clinical criteria to diagnose this entity.[147] Ludwig's angina is a cellulitis, not a focal abscess, that always involves both the sublingual and submandibular spaces and is frequently bilateral; produces gangrene or serosanguinous phlegmon, but little or no frank pus;



VIEW IMAGE

FIGURE 27-42 Submandibular gland duct calculus with abscess and duct obstruction. Axial contrast-enhanced CT scan demonstrates a calculus with surrounding hypoattenuating fluid density material (pus) (*arrow*). There is significant surrounding edema and a mass effect. Myositis of the left hyoglossus (*H*) and mylohyoid (*M*) muscles is identified compared to the normal contralateral mylohyoid (*black dots*) and hyoglossus (*white dots*) muscles.

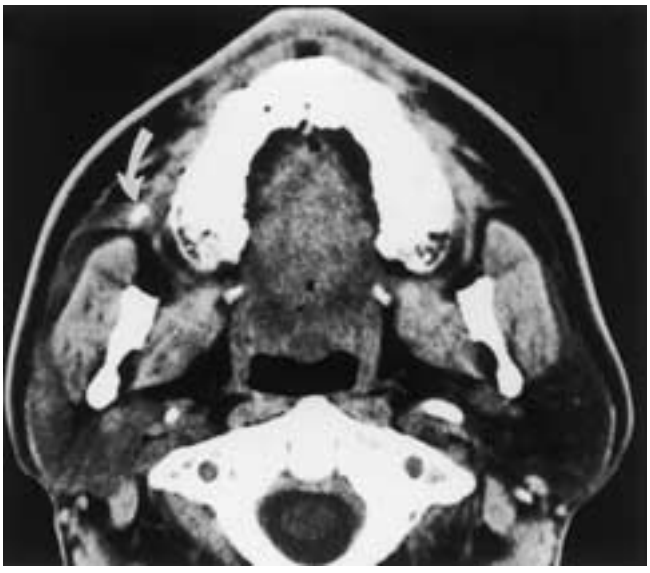


FIGURE 27-43 Calculus in the right parotid duct. Axial noncontrast-enhanced CT scan demonstrates a small calculus in the distal portion of Stensen's duct (*arrow*). Dilated intraglandular ducts are not identified on this image. However, the attenuation of the right parotid gland is higher than that of the normal left parotid gland. This reflects congestion, edema, and/or infection. (Courtesy of Dr. Deborah Reede.)

involves connective tissue, fascia, and muscle but not glandular structures; and is spread by contiguity, not lymphatics. The main role of imaging is to evaluate the integrity of the airway and document the presence of gas-forming organisms, underlying dental infection, and possibly drainable neck abscesses (Fig. 27-49).[146]

Reactive or suppurative adenopathy involving the submandibular and submental lymph nodes is commonly seen in association with oral cavity infections or as part of a more systemic process involving multiple lymph node chains. Submandibular and submental lymph node chains receive drainage from the chin, lips, cheeks, floor of the mouth, and oral tongue, and foci of infection within these regions should be sought.

HIV Involvement of the Oral Cavity

Among the protean manifestations of HIV infections in the extracranial head and neck, parotid gland lymphoepithelial cysts with associated diffuse cervical adenopathy has been shown to be a reliable predictor of HIV infection.[148, 149] More recently, cases of these cysts involving the submandibular glands have also been reported (see Chapter 39).[150–152] In some of these reported cases, parotid cysts were present, either synchronously or preceding the development of submandibular cysts, but in other reports, the presence or absence of associated parotid cysts was not noted.

A wide variety of opportunistic infections affecting the oral cavity occur in association with AIDS.[153] Oral candidiasis, a superficial fungal infection (*Candida albicans*), also termed *thrush* in its most common form, is one of the most frequent infections in this population. Hairy leukoplakia, a manifestation of the Epstein-Barr virus, typically appears as an isolated white plaque on the lateral margin of the oral tongue. Herpes simplex viral infections may produce deep, painful ulcerations. All of these oral infections are usually readily diagnosed by visual inspection. Imaging is reserved for those patients in whom there is a suspicion of disease spread to deeper tissues of the face or to assess the integrity of the mandible and maxilla.

Bacillary epithelioid angiomatosis, although most often occurring on the skin, has also been reported to affect the oral cavity.[154, 155] The causative organism is *Bartonella henselae*, a rickettsia-like organism. The lesion may resemble Kaposi's sarcoma, both clinically and microscopically, and is composed of areas of prominent vascular proliferation. It most often presents as a cutaneous lesion similar to a pyogenic granuloma.

Ranulas

Ranulas, also termed *mucoceles* or *mucous retention cysts* of the floor of the mouth, are of two varieties. The simple variety occurs in the floor of the mouth above the mylohyoid muscle in the region of the sublingual gland and is a true epithelium-lined cyst. These simple ranulas are usually due to obstruction of a minor salivary gland or of the

Only portions of the duct are visible on these images. There is also ductal dilatation within the left parotid gland best seen in (**B**).

sublingual gland. A ''diving'' or ''plunging'' ranula follows rupture of the simple ranula's wall. As such, these ranulas are not true epithelium-lined retention cysts but are pseudocysts lined by dense connective or granulation tissue.[156, 157] The extravasated mucus is most often directed posteriorly into the submandibular region, but occasionally it may dissect into the adjacent upper cervical soft tissues. These lesions may, therefore, present as masses in either the submental or submandibular regions. Ranulas are discussed further in Chapter 39.

On CT, ranulas are usually thin-walled unilocular, well-defined, nonenhancing, cystic-appearing lesions of low attenuation (Fig. 27-50).[158, 159] They have homogeneously low T1-weighted and high T2-weighted MR signal intensities (Fig. 27-51).[160, 161] When simple, they are confined to the sublingual region. When diving, the bulk of the ranula is typically identified in the submandibular region, although a portion of the lesion is usually identified in the sublingual region, suggesting the diagnosis (Fig. 27-52).[158] Rarely, ranulas may dissect across the midline between the mylohyoid and geniohyoid muscles, and present clinically as bilateral masses (Fig. 27-53).[162, 163] A completely intralingual ranula has also been reported (Fig. 27-54).[161]

Occasionally, the distinction between a plunging ranula in the submandibular space, with little or no visible sublingual component, and a second branchial cleft cyst may be problematic. Careful evaluation of the location of the cystic mass in relation to the submandibular gland may be helpful in making this distinction. Whereas the bulk of a plunging ranula typically lies medial to the submandibular gland and displaces it laterally (Fig. 27-55A), second branchial cleft cysts are usually located posterior to the gland, displacing it anteriorly (Fig. 27-55B).

Rarely, sialolithiasis, trauma, or tumoral obstruction of the submandibular gland duct system may lead to disruption of the duct, with extravasation of mucus into adjacent tissues. This incites an inflammatory reaction and is eventually lined with granulation tissue, forming a pseudocyst (Figs. 27-56 and 27-57). These have been termed *mucoceles of the extravasation type*, with imaging and histologic characteristics paralleling those of plunging ranulas of sublingual origin.[164] The epicenter of these mucoceles is usually not the same as that of the plunging ranula, which is typically at the posterior border of the mylohyoid muscle, displacing the submandibular gland laterally. These extravasation mucoceles are more commonly identified lateral and/or inferior to the gland, in the

submandibular and submental regions. Differential considerations of cystic-appearing lesions in the sublingual and submandibular regions include dermoid cysts, thyroglossal duct cysts, and cystic lymphangiomas.

Benign Lesions

Pleomorphic Adenomas

Pleomorphic adenomas (benign mixed tumors) are the most common benign glandular tumors of the oral cavity and are characterized by the presence of both mesodermal and glandular tissue. Although the majority of pleomorphic adenomas occur in the parotid gland, 8% arise within the submandibular gland, 0.5% involve the sublingual gland, and 6.5% occur in minor salivary glands situated throughout the upper aerodigestive tract. Only the gingiva and the most anterior portion of the hard palate are relatively devoid of these glands.

On CT, pleomorphic adenomas are usually well demarcated, homogeneous, and slightly hyperdense to muscle on noncontrast images (Fig. 27-58). Typically, there is no significant enhancement. Occasionally, the medial margin of a submandibular or sublingual pleomorphic adenoma may be poorly defined, suggesting a more aggressive lesion (Fig. 27-58).[165] When the hard palate is involved, there is usually a surrounding rim of well-defined cortical bone produced by the slow tumor growth and adjacent bone remodeling (Fig. 27-59). Large lesions may be inhomogeneous and have areas of necrosis, cystic changes, and amorphous calcification.

On MR imaging, pleomorphic adenomas are usually

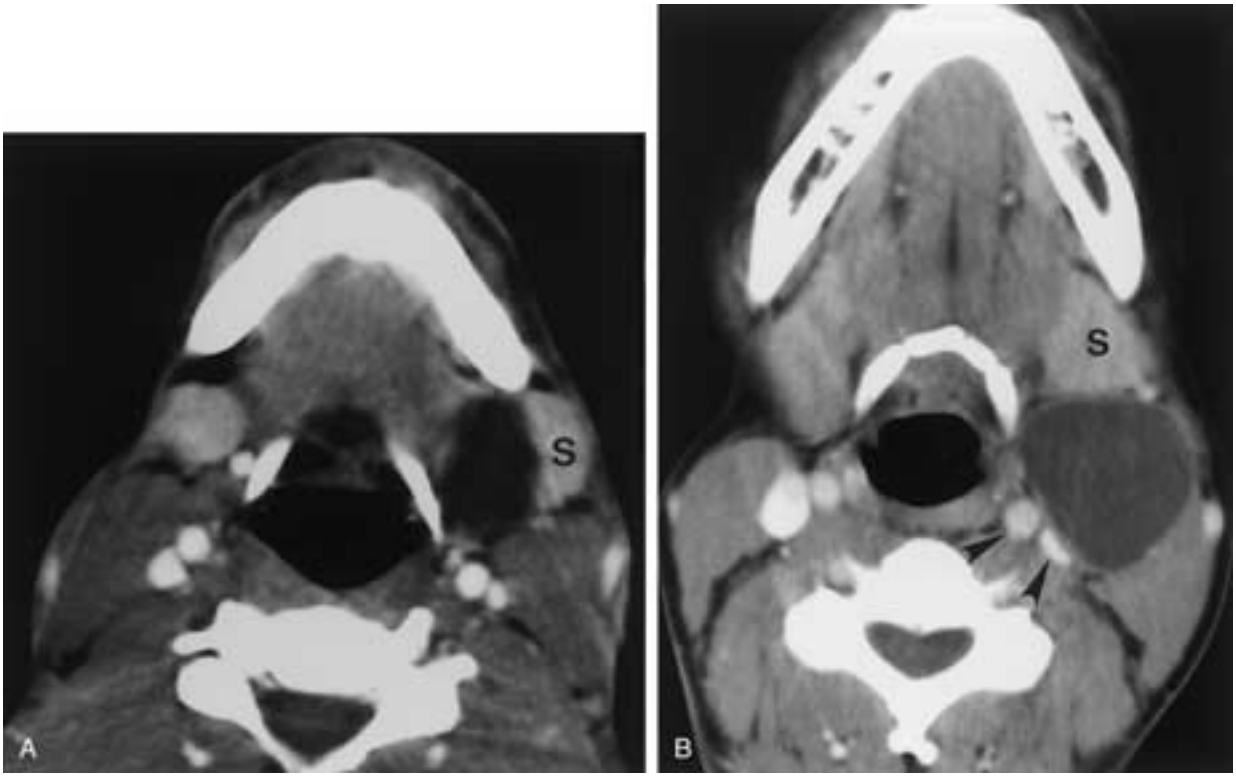
FIGURE 27-54 Intralingual ranula. Midsagittal T1-weighted image demonstrates a cystic lesion replacing the distal half of the oral tongue. The lesion is hypointense on T1-weighted images, and it became markedly hyperintense in a very homogeneous fashion on the heavily T2-weighted image (not shown), suggesting the fluid nature of the mass. (From Silverstein MI, Castillo M, Hudgins PA, et al. MR imaging of intralingual ranula in a child. J Comput Assist Tomogr 1990;14:672–673.)

isointense to muscle on T1-weighted images and become hyperintense on progressively more T2-weighted sequences.[165] Varying signal intensities within these tumors reflect their heterogeneous composition, and cystic change, necrosis, and hemorrhage may all be encountered. Excisional biopsy and incomplete resection are not advocated for treatment of these lesions, as they increase the likelihood of recurrence (Fig. 27-60). These lesions are discussed in greater detail in Chapter 39.

Aggressive Fibromatosis

Tumors of fibrous origin include a variety of histologies ranging from simple keloids at the benign end of the spectrum to fibrosarcomas at the malignant end. Between these extremes is aggressive fibromatosis, an extraabdominal desmoid ''tumor.''[166, 167] Termed *juvenile fibromatosis* by Stout and *aggressive infantile fibromatosis* by Enzinger, this entity represents one of the most complex problems in the classification of fibrous lesions. Several patterns are identified microscopically that essentially reflect progressive stages of fibroblast differentiation. Distinction between the more cellular varieties of fibromatosis and well-differentiated infantile fibrosarcoma may be extremely difficult, perhaps impossible.[168] Terms including *aggressive fibromatosis*, *differentiated fibrosarcoma*, and *fibrosarcoma-like fibromatosis* have all been applied to these lesions.[168] This topic is discussed further in Chapter 41.

Approximately 11% of infantile fibromatosis cases occur in the extracranial head and neck, primarily in young children, during the first or second year of life. There is a slightly higher prevalence in boys than in girls. The neck and supraclavicular regions are most commonly affected.[169] The oral cavity, nasal cavity, paranasal sinuses, nasopharynx,



VIEW IMAGE

FIGURE 27-55 Ranula versus second branchial cleft cyst. Axial contrast-enhanced CT scans demonstrate characteristic displacements by a ranula (**A**) and a second branchial cleft cyst (**B**). The ranula displaces the submandibular gland (*S*) laterally, while the typical second branchial cleft cyst displaces it anteriorly. Both may produce a mass effect on the sternocleidomastoid muscle if large enough, but the second branchial cleft cyst will often displace the carotid space structures posteromedially (*arrowheads* in **B**).

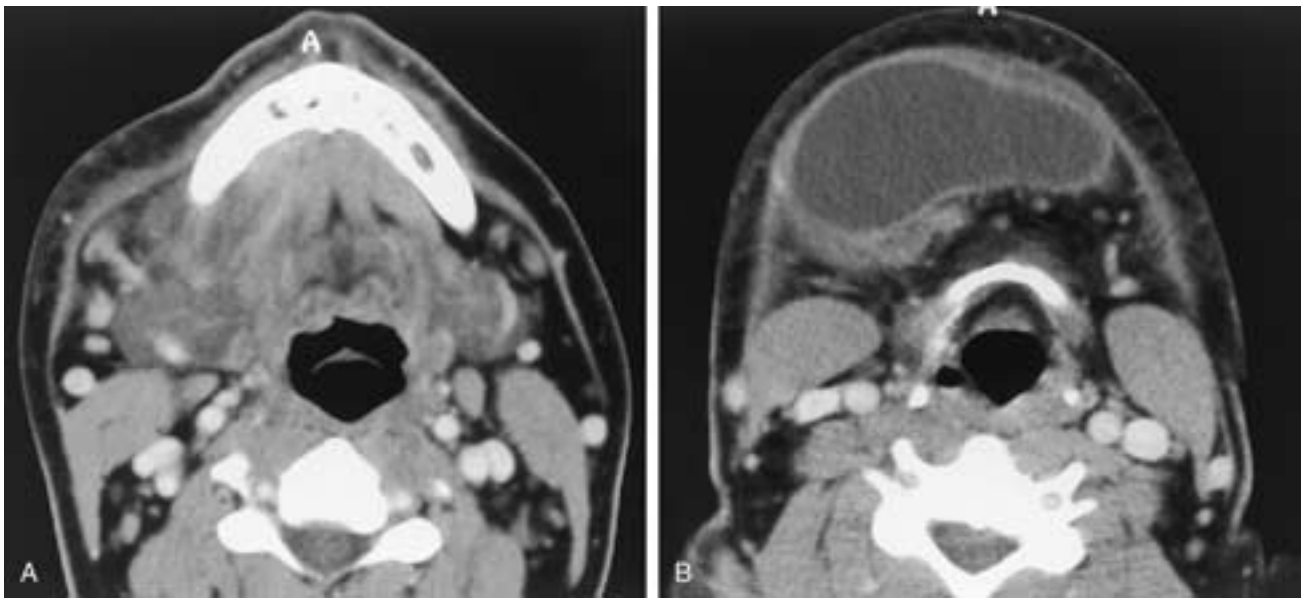
FIGURE 27-56 Extravasation mucocele. Serial contrast-enhanced CT images (**A** and **B**) demonstrate a cystic lesion in the right submandibular space, clearly lateral and inferior to the mylohyoid muscle. The mucocele wraps around the posterior margin of the mandible. The bulk of the mucocele is at the level of the hyoid bone.

and larynx are involved much less frequently.[170] Rare reports of fibromatosis involving the tongue also exist.[171–173] As a group, these lesions tend to manifest much more aggressive behavior than those that originate from the anterior abdominal wall because they infiltrate muscles and encase adjacent nerves and vessels.[1] Cases of head and neck fibromatosis extending into the epidural space and even intracranially have been reported.[174–176] Although aggressive fibromatosis has no malignant potential and does not metastasize, it manifests innate local aggressiveness and a high rate of recurrence after incomplete surgical resection. Recurrences after a delay of many years have also been reported.[177]

Aggressive fibromatosis arises as a solitary mass within



VIEW IMAGE

FIGURE 27-63 Aggressive fibromatosis. (**A**) Axial T1-weighted MR image demonstrates more heterogeneity in this lesion than that seen in Figure 27-62, reflecting its dense fibrous content. This is impressive on the coronal T2-weighted image (**B**), as a significant portion of the lesion is markedly hypointense. T1-weighted image after contrast enhancement in the sagittal plane (**C**) demonstrates very heterogeneous enhancement. The true craniocaudad extent of the lesion is best appreciated on the sagittal image (**C**), which demonstrates involvement up to the skull base. Imaging 3 years later (after extensive treatment) with contrast-enhanced, fat-suppressed, T1-weighted imaging in the axial (**D**) plane reveals a remarkable decrease in the size of the lesion, with only an area of residual dense fibrous tissue remaining (*arrows*).

Copyright © 2003, Mosby, Inc. All rights reserved.

areas of signal void that may be identified on both T1-weighted and T2-weighted images, probably reflecting dense collagen, are considered the hallmark of this entity (Fig. 27-63).[182] There is usually some degree of enhancement following contrast administration. It is probable that the spectrum of appearances on MR imaging is related to the relative amounts of fibroblast proliferation, fibrosis, and collagen contained within the lesion.[183]

Rhabdomyomas

Rhabdomyomas are rare benign tumors of striated muscle, most of which occur in the extracranial head and neck. In contrast to cardiac rhabdomyomas, considered to be hamartomatous lesions and often associated with tuberous sclerosis, extracardiac rhabdomyomas have no association with this syndrome. Extracardiac rhabdomyomas are subdivided clinically and morphologically into two histologic types: adult and fetal.[184] Adult rhabdomyomas occur predominantly in middle-aged men and have a predilection for the base of the tongue, floor of the mouth, larynx, and pharynx. For this reason, it has been suggested that these lesions arise from the striated muscles of the third and fourth branchial arches.[185] Fetal rhabdomyomas usually occur in children under the age of 3 years and also have a predilection for the extracranial head and neck. These fetal lesions may actually be hamartomatous malformations rather than true neoplasms. The preferred treatment for rhabdomyomas is complete surgical excision, which is often easily accomplished because these lesions tend to be well encapsulated.[186]

Rhabdomyomas are of muscle density on unenhanced CT and demonstrate enhancement following the administration of contrast.[187] On MR imaging, rhabdomyomas are isointense or slightly hyperintense to muscle on T1-weighted images, hyperintense on T2-weighted images, and enhance slightly following contrast administration (Fig. 27-64).

Lipomas

The ordinary lipoma is the most common tumor of mesenchymal origin. Only 13% arise in the extracranial head and neck; most are located in the posterior cervical region.[188] The remaining lesions, as a group, are rare, occurring primarily in the oral cavity, pharynx, parotid gland, and larynx. Within the oral cavity, lipomas represent only 1% to 4% of benign oral tumors and 1% of benign tongue tumors. These lesions are composed of mature fat cells arranged in lobules, separated by fibrous tissue septae, usually surrounded by a thin, fibrous capsule.[189] Some variants have been classified histologically, according to the kind and amount of tissue, other than fat, that may also be present.[190] Most common is the fibrolipoma, containing an increased amount of fibrous connective tissue between the fat cells. Other variants include angiolipoma, containing an excess of capillaries; myxolipoma, with wide areas of myxoid change; and chondrolipoma, the most uncommon of the variant lipomas, with osseous or cartilaginous change.[189]

Lipomas are more common in overweight individuals and tend to increase in size during periods of rapid weight gain, being most common below the clavicle in obese women over 40 years of age. In contrast, lipomas in men tend to occur after the seventh decade, primarily in the head and neck region.

Within the oral cavity, lipomas, in decreasing order of frequency, are encountered in the cheek, tongue, floor of the mouth, buccal sulcus, palate, lip, and gingiva, with one third to one half occurring in the cheek.[168, 190] Of those lesions that occur within the tongue, most arise within the oral tongue, as opposed to the tongue base. A huge oral tongue lipoma measuring $10 \times 9 \times 6$ cm, extending to involve the submandibular and sublingual regions, has been reported.[191]

These lesions have a virtually pathognomic, homogeneous, nonenhancing, low CT attenuation ranging from –65 to –125 HU (Figs. 27-65 and 27-66). The most common

differential diagnosis includes suprahyoid thyroglossal duct cysts, ranulas, and dermoid lesions, none of which have the typical low fat attenuation. Lipomas often displace and compress adjacent structures but rarely infiltrate them.[192] MR imaging of a typical lipoma demonstrates high signal intensity, consistent with fat, on T1-weighted images and lower T2-weighted signal intensity.

Nerve Sheath Tumors

The terminology used to classify nerve sheath tumors has been somewhat confusing. Schwannomas have been variously termed *neurolemmomas, neuromas, neurinomas,* and *perineural fibroblastomas*.[1] Additionally, some have applied the term *schwannoma* to encompass both neurolemmoma and neurofibroma, while others include schwannomas and neuromas in discussions of neurolemmoma.[193] However, schwannomas (neurolemmoma) and neurofibromas can be distinguished on a histologic basis.[1] Neither should be confused with neuromas, which represent an exaggerated repair response to neuronal injury in which a tangle of regenerating axons, fibrous tissue, and Schwann cells forms at the site of a severed nerve.[194]

The lesion insinuates among the normal structures of this region. *S*, Submandibular gland; *black dot*, sternocleidomastoid muscle; *M*, mylohyoid muscle.

Schwannomas

Approximately 13% of schwannomas occur in the extracranial head and neck; most are encountered in the lateral cervical region, with the sympathetic chain being the most common site of origin.[195, 196] In 1977, Gallo et al. reported 152 cases of oral schwannomas, 71 of them lingual.[197] In general, schwannomas tend to be somewhat more common in women and typically occur in the 30- to 40-year-old age group.[195] Most schwannomas appear as well-circumscribed, homogeneous, soft-tissue density masses on unenhanced CT and exhibit contrast enhancement. Larger lesions may contain one or more cystic areas and present a more variable CT appearance.[198] Schwannomas tend to be isointense to muscle on T1-weighted images and hyperintense on T2-weighted images.[193] The cystic components of larger schwannomas may be difficult to distinguish from the solid components on T2-weighted MR images because both manifest high signal intensity.[198] Enhancement following administration of contrast is the rule (Fig. 27-67).

Angiographically, schwannomas demonstrate a pattern of moderate hypervascularity, tortuous tumor vessels, and scattered contrast puddles without arteriovenous shunting or vascular encasement. Embolization has been shown to be a useful presurgical adjunct.[199]

Neurofibromas

Neurofibromas involving the oral cavity are rare, and most are associated with neurofibromatosis. Oral manifestations of neurofibromatosis are reported in only 4% to 5% of affected individuals, the tongue being the most common site of involvement.[200] Within the tongue, these rare lesions have been reported to involve either the lingual or the hypoglossal nerves or both.[201] Neurofibromas have a density similar to that of muscle on unenhanced CT studies and enhance following contrast administration. They are typically isointense to muscle on T1-weighted images and hyperintense on T2-weighted images.

Granular Cell Myoblastomas

Granular cell myoblastomas are considered to be of neurogenic origin, although they also contain skeletal muscle and histiocytes. Of these tumors, 50% involve the tongue or floor of the mouth, occurring primarily in young adults. The lateral tip or dorsum of the tongue is most often affected, with infiltration of surrounding tissues being common. The CT appearance is nonspecific, similar to that of squamous cell carcinoma. The MR imaging features, however, may be somewhat more specific because these lesions tend to exhibit low signal intensity on both T1-weighted and T2-weighted images, most likely reflecting their fibrous or skeletal components.[202]

Congenital epulides of the newborn are rare gingival tumors that most often occur along the alveolar ridge of the maxilla in newborn girls. Occasionally, these tumors may involve the mandible or may be multiple. Although the term *congenital gingival granular cell tumor* has been used in

FIGURE 27-67 Schwannoma in a patient with neurofibromatosis type 2 (probably of the incisive canal). **A**, Axial CT scan at a bone window setting demonstrates a cystic-appearing mass that has destroyed much of the left hard palate and portions of the left maxillary alveolus (*arrows*). Axial T1-weighted (**B**) and T2-weighted (**C**) MR images confirm the cystic nature of this lesion and demonstrate a fluid level within it (*arrows*). The T2-weighted image (**C**) actually shows three definite different density levels. Following contrast administration, an axial (**D**) image reveals well-defined rim enhancement.

reference to these legions, congenital epulides are more vascular, contain less conspicuous nerve bundles, occur exclusively in the pediatric population, and do not involve other organs, in contrast to granular cell myoblastomas.[203, 204] A single report by Koch et al. described the MR imaging appearance of a congenital epulis as heterogeneous, smooth, and well defined, with a signal intensity slightly greater than that of muscle on both T1-weighted and T2-weighted imaging.[205] Complete surgical excision is curative.

Exostoses

Torus palatinus is a benign thickening of the cortical and medullary bone on the oral surface of the hard palate. The nasal portion of the hard palate is unaffected. The exact etiology of this lesion is not known, but it may represent downward misdirection of underused growth potential of the palatal shelf.[206] Heredity appears to be a definite factor in the development of palatal tori. These lesions typically occur in the middle of the hard palate and extend to either side, approximately symmetrically, sparing the region of the greater palatine foramen. Tori grow as the patient grows until maturity at 20 to 30 years of age, although some may continue to grow in later decades of life. Females are affected twice as often as males after the newborn period.

Palatal tori have been subclassified by shape into flat, spindle, nodular, and lobulated varieties, flat and spindle shapes being the most common (86%).[206] Their size is extremely variable, ranging from flat lesions measuring only a few millimeters to large, lobulated lesions that may be 15 mm or larger. On CT, smaller lesions appear as dense cortical bone protruding inferiorly from the oral aspect of the hard palate, optimally demonstrated on scans obtained in the coronal plane (Fig. 27-68), whereas larger tori may

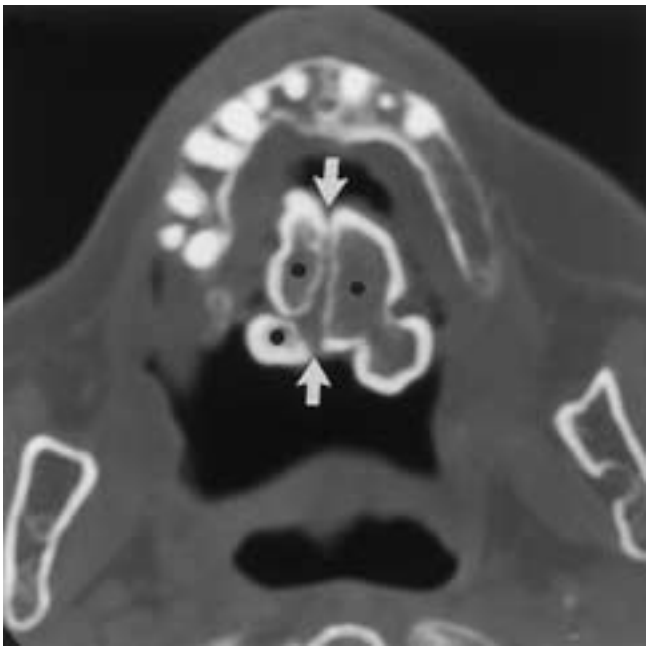
FIGURE 27-68 Torus palatinus. Coronal CT scan at a bone window setting shows a palatal torus composed only of dense cortical bone (*arrow*).

demonstrate cortical bone surrounding areas of cancellous bone, often with a midline fissure (Fig. 27-69).

Most tori remain asymptomatic, tending to be flat or spindle-shaped. Larger lesions, however, may promote food impaction within the grooves and lead to halitosis. Large palatal tori may restrict tongue motion and distort the oral airway, leading to speech disturbances, or may require resection prior to dental prosthesis placement to avoid poor adhesion or rocking of the prosthesis.[206]



VIEW IMAGE

FIGURE 27-69 Torus palatinus. Axial CT scan obtained at a bone window setting demonstrates a very large torus palatinus projecting into the upper aspect of the oral cavity. The torus is multilobulated, with multiple areas of well-corticated cancellous bone (*dots*). A midline fissure is also present (*arrows*). (Courtesy of Dr. Deborah Reede.)

Tori maxillaris and mandibularis occur more often in patients who have palatal tori than in the general population.[206] Torus maxillaris refers to unilateral or bilateral exostoses that may occur on either the buccal (torus maxillaris externa) or lingual (torus maxillaris interna) aspect of the maxilla (Fig. 27-70). Torus mandibularis occurs exclusively on the lingual aspect of the mandible, typically opposite the root of the second premolar in the region of the mental foramen (Fig. 27-70).[206]

Fibroosseous Lesions

Fibroosseous lesions are a challenging and diverse group of pathologic conditions that are difficult to classify and treat. There are no universally accepted criteria to distinguish these lesions absolutely from one another either clinically, radiographically, or histopathologically.[207, 208]

Many of these lesions are addressed elsewhere in this book but, given the high rate of involvement, if not exclusive involvement, of the maxilla and mandible by some of these entities, a brief discussion of fibroosseous lesions in this chapter on the oral cavity (including the maxilla and mandible) seems warranted.

The common denominator to all of the fibroosseous lesions is the replacement of bone with benign fibrous tissue containing varying amounts of (calcified) mineralized material. These lesions are basically divided into two main groups: fibrous dysplasia, a developmental lesion due to idiopathic arrest in the normal maturation of bone at the woven bone stage, and those lesions that have been postulated to originate from the periodontal ligament. Included in the latter group are central cementifying fibromas and periapical, focal, or florid cemento-osseous dysplasias.[207, 209] Some authors also include lesions such as osteomas, giant cell lesions, and osteoblastomas in discussions of fibroosseous lesions.[207, 210, 211]

Fibrous Dysplasia

Fibrous dysplasia is an idiopathic disorder in which there is an arrest of primitive fibrous stroma at the woven bone stage such that the normal replacement of immature woven bone by lamellar bone does not occur.[212] Osteoblasts are conspicuously absent. The medullary bone is replaced by poorly organized and loosely woven bone, which is manifest radiographically as obliteration of the medullary canal of involved bone associated with bone expansion and thinning of the overlying cortex. The disease may be monostotic (70%) (Figs. 27-71 and 27-72) or polyostotic (30%); the latter tends to occur at an earlier age and may be associated with the McCune-Albright syndrome.[212] Of the monostotic form, approximately 25% of cases involve the head and neck, the maxilla and mandible being the most common sites, while 40% to 60% of patients with the polyostotic form have involvement of the skull and facial bones (Fig. 27-73). Malignant transformation occurs following craniofacial irradiation in approximately 0.5% of cases, predominantly in the polyostotic form. The classic ''ground glass'' or ''frosted glass'' appearance of fibrous dysplasia on plain radiographs and CT is due to the myriad dispersed minute

Copyright © 2003, Mosby, Inc. All rights reserved.

spicules of bone within the lesion, which, as it is not encapsulated, blends imperceptibly into normal cortical bone.[210] The plain radiographic features have been classified into three patterns: pagetoid (56%), sclerotic (23%), and radiolucent or cystic (21%).[213] Fibrous dysplasia is typically hypointense on T1-weighted MR images and of variable signal intensity on T2-weighted images, ranging from low to intermediate to high.[214–216] In a study by Jee et al., 75% of lesions demonstrated central enhancement following contrast administration.[217]

(Central) Cementifying Fibroma

At one time the World Health Organization (WHO) separated central ossifying fibromas (COFs), considered to be tumors of osseous origin, from central cementifying fibromas (CCFs), considered to represent tumors of odontogenic origin. However, today there is general agreement that these two lesions merely represent histologic variants of the same lesion, and the 1992 WHO classification now groups them under a single designation as central cemento-ossifying fibroma (CCOF).[218] If the stroma consists primarily of osteoid tissue, the lesions are labeled *ossifying fibromas*. Lesions with connective tissue stroma consisting primarily of foci of basophilic masses of cementum-like tissue are termed *cementifying fibromas*, and those with a combination of osteoid formation and cementum-like tissue within the stroma are termed *cemento-ossifying fibromas*.[219] CCOFs occur almost exclusively in the facial bones of the skull. Seventy percent or more occur in the mandibular molar/premolar area, and there is a definite female predominance (5:1).[209] There is convincing evidence that these lesions originate from elements of the periodontal ligament.[209] CCOFs tend to occur in an older age group (the third and fourth decades) than fibrous dysplasia and are more invasive. Histologic differentiation between CCOFs and fibrous dysplasia is often difficult, and many overlapping features exist. However, two features are noted as distinguishing CCOF from fibrous dysplasia: most of the disorganized bony spicules in CCOFs are composed of lamellar bone rather than immature woven bone, as in fibrous dysplasia, and osteoblasts rim the trabeculae in CCOFs, whereas they are absent in fibrous dysplasia.[210] On CT, CCOFs are usually well-circumscribed, expansile, unilocular lesions with discrete areas of calcification and ossification. Their MR imaging appearance is variable, but most reported lesions are iso- or hypointense to muscle on T1-weighted images and very hypointense on T2-weighted images secondary to the calcific and fibrous nature of the lesions and resulting low free water content (Fig. 27-74).[220]

There is a juvenile aggressive form of CCOF that presents in childhood (approximately 80% of patients are under 15 years of age), more commonly involves the maxilla rather than the mandible, and is more aggressive clinically, exhibiting rapid growth.[209, 221, 222] Pathologically, these lesions tend to be more vascular than the typical CCOF.

VIEW IMAGE

FIGURE 27-72 Maxillary monostotic fibrous dysplasia. Coronal CT scan at a bone window setting reveals enlargement of the right maxillary alveolus and hard palate with distortion of dentition. The right maxilla is almost double the size of the left. A very large intrasinus component is present, the appearance of which differs from that in the alveolar bone.

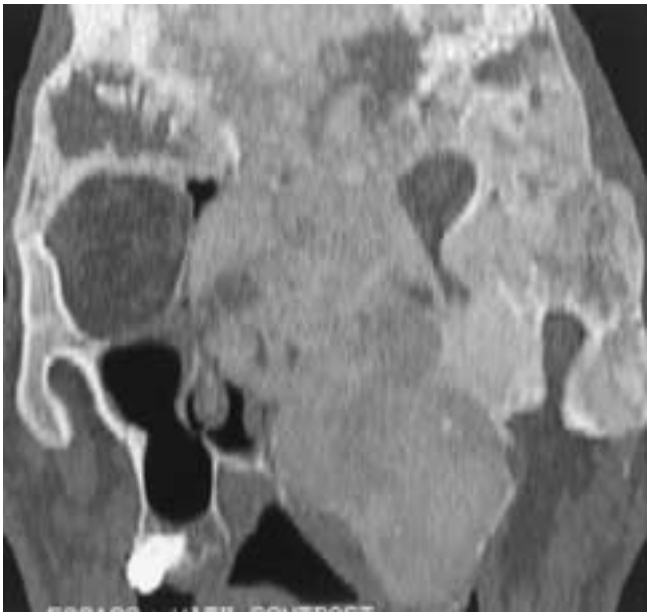

FIGURE 27-73 Diffuse skull and facial fibrous dysplasia. This coronal CT scan reveals the extensive involvement of the midface and left facial bones with obliteration of the left maxillary sinus, most of the nasal cavity, ethmoid, and frontal air cells, and severe left orbital encroachment. This pattern of severe facial bone involvement is termed *leontitis ostea*.

Osteomas

Osteomas are well-differentiated benign tumors consisting predominantly of cancellous or compact bone that increase in size by continuous formation of bone.[223, 224] They are most commonly encountered within or on the periphery of membranous bones of the skull, face, and jaws. Their pathogenesis is obscure, although the combination of trauma and muscle traction has been proposed.[225] Solitary osteomas of the mandible and maxilla are uncommon and occur more often in the mandible.[225] Multiple osteomas are encountered in association with Gardner's syndrome. Most lesions are very slow-growing and are identified after the age of 25 years.

Osteomas are rare within the soft tissues of the extracranial head and neck, especially the tongue. In a review of the English-language literature in 1989, Nash et al. reviewed 31 previously reported cases of lingual osteomas and added one of their own.[226] These lesions predominate in the third decade, and 75% occur in females. The majority of reported lingual osteomas occur at the junction of the anterior two thirds and the posterior one third of the tongue, in the region of the circumvallate papillae or foramen cecum (Fig. 27-75). Because of its location, a lingual osteoma may be mistaken clinically for lingual thyroid tissue.[227]

Giant Cell Lesions

Much controversy exists regarding the terminology and nature of central giant cell lesions of the jaws. The histologic differentiation between central giant cell granulomas (CGCGs) and central giant cell tumors (CGCTs) is rather

obscure as there are only gradual differences and no absolute criteria for differentiation.[228] These two entities probably represent a continuum of a single disease process.[229] Although the term *granuloma* is still often used, some have suggested the designations of nonaggressive and aggressive forms, the aggressive form behaving more like the classically described CGCT. In the jaws, CGCG may arise in association with Paget's disease, whereas in the skeleton, CGCT is associated with this disease.[230]

CGCG, as it has been classically described, is an uncommon nonneoplastic fibroosseous lesion, accounting for less than 7% of all benign jaw lesions. It is found almost exclusively in the mandible, maxilla, or associated structures, is most common in the anterior mandible, and often crosses the midline.[231, 232] This lesion occurs most frequently in young adults (50% occur prior to age 30), and there is a definite female predilection. The CT features of these lesions in 10 children reported by Bodner and Bar-Zin fell into two distinct patterns: a unilocular osteolytic lesion (Fig. 27-76) or multilocular with septations coursing through the lesion (Fig. 27-77).[232] The MR imaging features are relatively nonspecific and do not allow differentiation from other benign lesions of the jaw such as Langerhans' histiocytosis (Figs. 27-78 and 27-79).

Benign Odontogenic Lesions

A variety of cysts and benign neoplasms arising from various components of dental structures are encountered in the mandible, the maxillary alveolus, and the hard palate. The *radicular cyst* (periodontal, periapical cyst) is the most common odontogenic cyst. It arises at the apical end of an erupted, devitalized, infected tooth in a preexisting periapical granuloma.[233] The *dentigerous cyst* represents 95% of follicular cysts and develops from the enamel organ of an unerupted tooth after the crown has developed.[233, 234] These are also usually well-defined, corticated, round, unilocular cystic lesions, and the tooth crown is typically identified within the cyst (Fig. 27-80), although large cysts may be multilocular. The *primordial cyst* represents the remaining 5% of follicular cysts and results from degeneration of the enamel organ with absence of the tooth crown. This cyst is also typically unilocular and well circumscribed. *Odontogenic keratocysts,* representing 5% to 15% of all jaw cysts, are most often of the parakeratotic variety. They are rapidly growing, aggressive lesions that contain keratin, occur two to four times more often in the mandible (usually the body and ramus) than in the maxilla, and are associated with basal cell nevus (Gorlin's syndrome) and Marfan's syndrome. These lesions have the highest rate of recurrence of any odontogenic cyst after excision (12% to 63%).[234, 235] Squamous cell carcinomas arising in odontogenic keratocysts have been reported.[236] Keratocysts tend to be unilocular and expansile radiolucent lesions with sclerotic, sharply defined smooth or scalloped margins (Fig. 27-81). When they occur in the maxilla, keratocysts may elevate the floor of the maxillary sinus, similar to dentigerous cysts.[237] On MR imaging, keratocysts demonstrate variable signal intensity, usually intermediate or high on T1-weighted images, depending upon the amounts of contained epithelial debris and blood degradation products. These lesions typically brighten and demonstrate heterogeneous intermediate signal intensity on T2-weighted images.[235, 237] Their walls are thin and usually demonstrate weak enhancement, features that allow their distinction from ameloblastomas.[235]

Ameloblastomas are benign, locally aggressive, nonencapsulated, infiltrating neoplasms of odontogenic origin. They are thought to originate from enamel organ-like tissue composed of epithelial elements, but these lesions do not differentiate sufficiently to form enamel and may not even contain ameloblasts.[238] They occur in the mandible about 85% of the time, usually present in the fourth or fifth decade, and show no definite sex predilection.[233, 234, 239, 240] A variety of benign histologic variants have been described, as has a metastasizing malignant form (ameloblastic carcinoma), discussions of which are beyond the scope of this chapter.[240] On CT, ameloblastomas may be unilocular, well circumscribed, and radiolucent in younger patients (average age, 26 years), but they grow to become multiloculated, expansile neoplasms as the patient ages (average age, 38 years). The locules may be only 1 cm in size, producing an overall honeycomb appearance, typically nonenhancing and inhomogeneous. Lesions with larger locules have been described as having a ''soap bubble'' appearance (Fig. 27-82).[233, 238] On MR imaging, these lesions are usually of slightly inhomogeneous intermediate signal intensity on T1-weighted images, largely isointense with muscle, and of inhomogeneous higher signal intensity on T2-weighted images with lower signal intensity septations.[238] Areas of signal void, corresponding to areas of calcification, may be present, and the solid portions of the tumor enhance markedly.[235]

Miscellaneous Benign Lesions

Incisive Canal (Nasopalatine Duct) Cysts

These lesions are one of a group of fissural cysts that develop from trapped epithelium in fusion lines during facial development. Incisive foramen/canal cysts are the most common developmental cysts of the maxilla.[233] The size of the normal incisive foramen varies greatly, averaging 3 by 3 mm.[241] The majority of the time, the incisive foramen does not have a cortical margin. However, when a cyst is present,

Copyright © 2003, Mosby, Inc. All rights reserved.

the incisive foramen or canal will appear enlarged, often with a sclerotic margin on CT. This is best appreciated on axial images (Fig. 27-83). The cysts develop from proliferation of epithelial or mucous cells within the nasopalatine canal.[233] This permits secretion of mucoid material and explains the signal characteristics noted within these cysts on MR images (Fig. 27-84). The signal is typically hyperintense on T1-weighted images and falls off somewhat on T2-weighted images, but this is variable and reflective of the mucoid content of the cysts. These lesions are located within the midline of the hard palate when they involve the incisive canal rather than the incisive foramen, expanding the palate, usually with a well-defined margin, and are easily identified on MR imaging.

Osteochondroma (Osteocartilaginous Exostosis)

Osteochondromas are the most common benign tumors of bone, representing 35% to 50% of all benign bone tumors.[225] In the craniofacial region, however, these lesions are quite rare, reported in the skull base, maxillary sinus, zygomatic arch, and mandible.[242] Mandibular osteochondromas are most often located on the coronoid process, followed by the condyle, but have also been reported to occur in the ramus, body, and symphyseal regions.[243–246] These exophytic lesions arise from the cortex of bone and are covered by a cartilaginous cap.

Chondroma

Chondromas are benign tumors of cartilage. Uncommon within the oral cavity, most chondromas occur in the hard palate and alveolar ridge or involve the condyle or coronoid process of the mandible. Only a few extraskeletal oral chondromas have been reported, the tongue being the most common site.[247] These lesions most often affect the lateral borders or dorsum of the oral tongue and occur equally in both sexes; the mean age at presentation is 31 years.[247] The etiology of these cartilaginous lesions in the tongue is not yet clearly established.

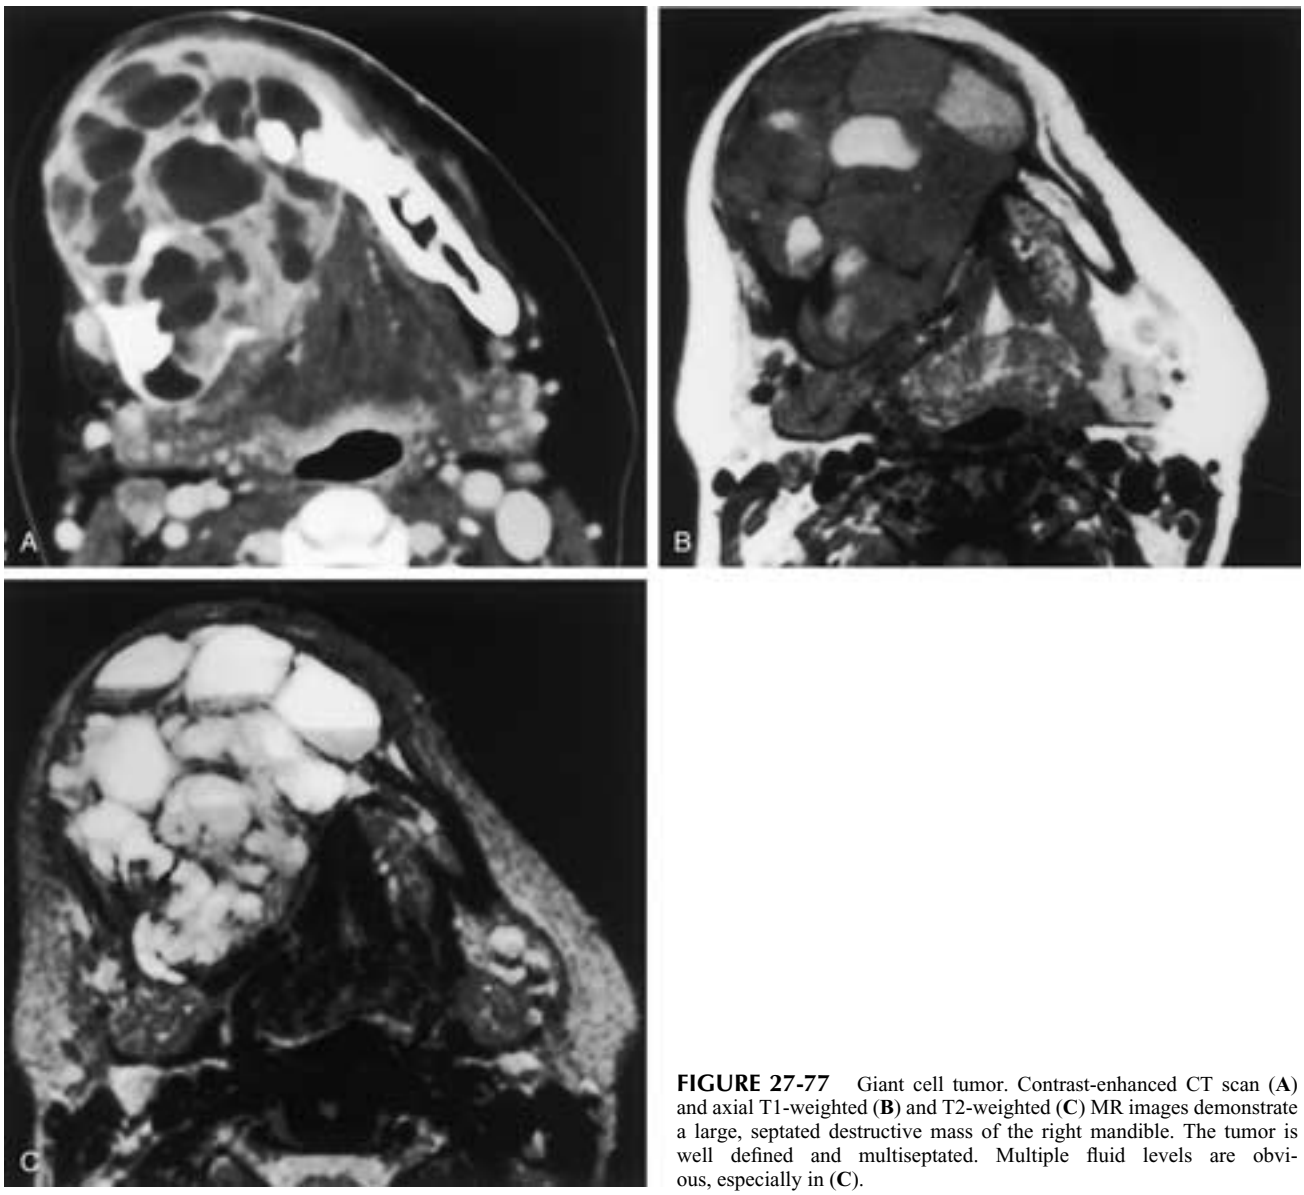

FIGURE 27-77 Giant cell tumor. Contrast-enhanced CT scan (**A**) and axial T1-weighted (**B**) and T2-weighted (**C**) MR images demonstrate a large, septated destructive mass of the right mandible. The tumor is well defined and multiseptated. Multiple fluid levels are obvious, especially in (**C**).

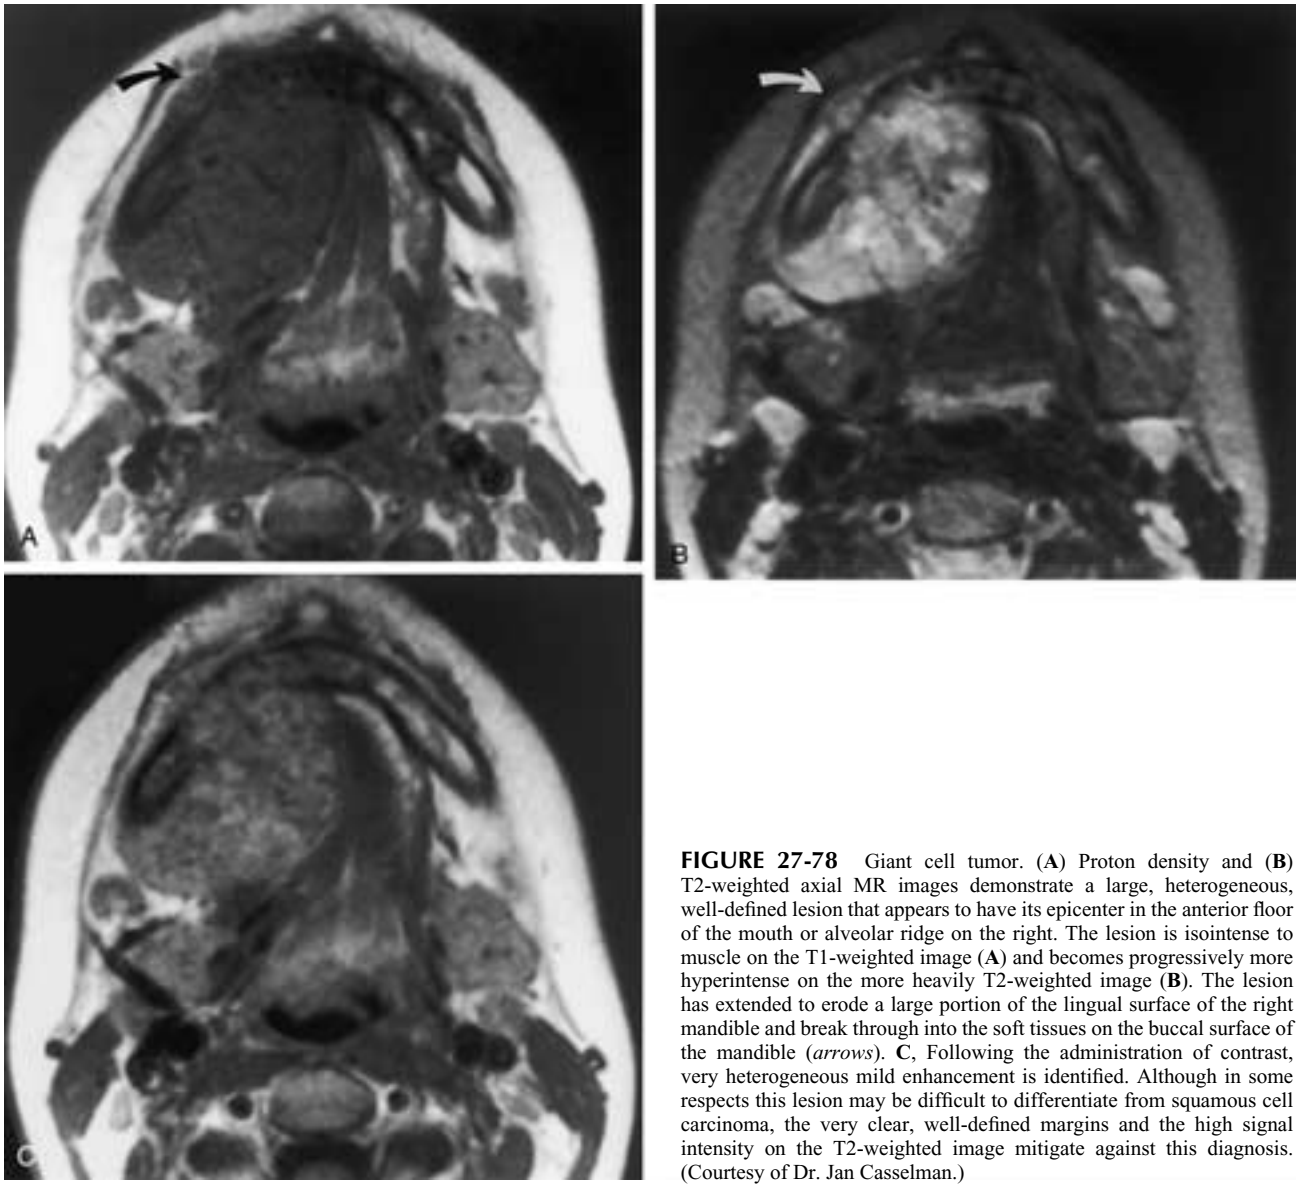

FIGURE 27-78 Giant cell tumor. (**A**) Proton density and (**B**) T2-weighted axial MR images demonstrate a large, heterogeneous, well-defined lesion that appears to have its epicenter in the anterior floor of the mouth or alveolar ridge on the right. The lesion is isointense to muscle on the T1-weighted image (**A**) and becomes progressively more hyperintense on the more heavily T2-weighted image (**B**). The lesion has extended to erode a large portion of the lingual surface of the right mandible and break through into the soft tissues on the buccal surface of the mandible (*arrows*). **C**, Following the administration of contrast, very heterogeneous mild enhancement is identified. Although in some respects this lesion may be difficult to differentiate from squamous cell carcinoma, the very clear, well-defined margins and the high signal intensity on the T2-weighted image mitigate against this diagnosis. (Courtesy of Dr. Jan Casselman.)

VIEW IMAGE

Epithelioid Hemangioendothelioma

Only five cases of these rare lesions involving the oral cavity have been reported.[248–251] Three tumors involved the gingiva, one involved the tongue, and one involved the palate. These lesions are soft-tissue vascular neoplasms characterized by proliferation of endothelial cells with an epithelioid morphology. Their biologic behavior is considered borderline in that they have an indolent course with a potential for recurrence but rarely metastasize.

Asymmetric Maxillary Sinus Pneumatization

Pneumatization of the maxillary sinus is quite variable, and patients have been examined for asymmetry of the hard palate on physical examination produced by extensive asymmetric maxillary sinus pneumatization. Figure 27-85 is of a 43-year-old man referred for CT by his dentist to exclude a mass on the left aspect of the hard palate because the contour of the palate was extremely asymmetric.

Located in a more anterior position, this keratocyst replaces much of the hard palate on the right and elevates the maxillary sinus floor (*arrows*) but does not fill the entire sinus. No associated unerupted tooth crown is seen, but there is a fully erupted canine tooth that is significantly malpositioned by the cyst (*dots*). (Courtesy of Dr. Thomas Underhill.)

Malignant Lesions

Only 7% of oral cavity lesions are malignant, but of these lesions, squamous cell carcinoma accounts for 90%.[252] Other malignancies encountered in this region include minor salivary gland tumors (adenoid cystic carcinoma, adenocarcinoma, and mucoepidermoid carcinoma), lymphomas, other rare tumors including sarcomas (liposarcoma, rhabdomyosarcoma), and a variety of common and uncommon neoplasms of the mandible. Most masses within the oral cavity, both benign and malignant, are amenable to direct clinical examination, which is the best means by which to detect mu-

cosal involvement. The primary purpose of imaging these lesions is to detect their deep or submucosal extent. Staging of primary malignancies of the oral cavity is uniformly based on the TNM system developed by the American Joint Commission on Cancer Staging (Table 27-2).[252]

Squamous Cell Carcinoma

Squamous cell carcinoma (SCCa) typically affects men aged 50 to 70 years with a long history of alcohol and tobacco abuse.[253, 254] Heavy-drinking smokers have a risk of developing SCCa 6 to 15 times greater than that of abstainers.[254] Approximately two thirds of the tumors are moderately or far advanced at the time of initial presentation. The behavior of SCCa of the oral cavity differs somewhat from that of SCCa of the oropharynx. The mucosa of the oropharynx, posterior to the circumvallate papillae, is derived from endoderm and has a tendency to be affected by less well-differentiated, aggressive carcinomas. The squamous epithelium within the oral cavity, however, is derived from ectodermal elements and tends to be affected by less aggressive lesions.[1, 255] Differences in lymphatic drainage also exist.

Although SCCa may arise from any mucosal surface, it has a tendency to affect three specific intraoral areas: the floor of the mouth, the ventrolateral tongue, and the soft palate complex (soft palate proper, retromolar trigone, anterior tonsillar pillar).[254, 256] Of 222 asymptomatic SCCa in 161 drinking smokers (excluding 15 involving the lip), 201 (97%) were identified in these three locations: 101 (50%) in the floor of the mouth, 64 (32%) in the soft palate complex, and 6 (18%) on the ventrolateral tongue.[257] Only 6 of the 222 lesions were not located in one of these three high-risk areas (excluding the lip). Frequency according to site of occurrence, as reported by Lederman from a study of 14,253 patients, is listed in Table 27-3.[258] The observation that the vast majority of oral cavity SCCa arise from the relatively limited most dependent portions of the oral cavity mucosa may be due to a variety of factors. Two of these dependent regions (floor of the mouth and oral tongue) are continuously bathed in a pool of saliva, which may serve as a reservoir of exogenous carcinogens, primarily derived from the irritating effects of alcoholic beverages and tobacco. Individuals with SCCa of the oral tongue and floor of the mouth have the highest rates of alcohol consumption. Although the soft palate complex is not a dependent reservoir, it is possible that inhaled tobacco smoke is concentrated in this area and exerts a direct carcinogenic

effect.[254] In addition, in contrast to the relatively thick layer of squamous cell epithelium, containing well-developed rete pegs and a prominent superficial keratin layer that lines most of the oral cavity, these high-risk areas are lined by thin, relatively atrophic mucosa with shallow or nonexistent rete pegs and little surface keratin.[147, 254, 256]

Primary floor of the mouth SCCa, or extension from adjacent SCCa into the floor of the mouth, carries a potential for involvement of nerves and vessels within the neurovascular bundles. Vascular and perineural invasion have adverse effects on overall patient survival due to reduced local and regional tumor control.[259, 260] Vascular invasion is associated with an increased likelihood of cervical nodal metastases, which in turn is the most reliable prognostic indicator for patients with SCCa.[261] Perineural invasion is often clinically silent and permits tumor extension beyond the expected tumor margins, often resulting in positive margins at surgical resection and a greater likelihood of recurrence.[262] Most authors believe that neurovascular invasion is indicative of tumors with aggressive biological behavior and greater metastatic potential.[260, 263] Elective neck dissection, radiation therapy of cervical nodes, or both is therefore recommended.[264]

It has been shown that CT can reliably predict neurovascular invasion by SCCa in this region.[261] Aggressive tumor margins, invasion of the sublingual space, and lesion location adjacent to neurovascular structures are all highly suggestive findings of neurovascular invasion. There is also a strong correlation between tumor size and neurovascular invasion such that tumors with a mean diameter of at least 2 cm on CT are more likely to be associated with neurovascular invasion.[261]

It is estimated that 30% to 65% of patients with oral cavity SCCa have nodal involvement at the time of initial presentation, the presence or absence of which is the single most important prognostic indicator in this patient population.[2, 265–268] For this reason, all of the cervical lymph node chains should be imaged at the same time that the primary tumor is imaged.[269] This may be accomplished by either CT or MR imaging, although currently, MR imaging is not as accurate as CT in its ability to demonstrate either extranodal tumor spread or central necrosis.[270, 271]

On CT, SCCa has a density similar to that of muscle and enhances, usually moderately, following administration of contrast. These tumors are also identified by their distortion of the normal structures and surrounding fat planes. Squamous cell carcinomas possess MR signal intensities similar to those of muscle on T1-weighted images and inhomogeneous increased signal intensity on T2-weighted images. Tumors enhance to some degree with gadolinium.[272, 273] Nonenhanced T1-weighted MR imaging appears to provide the most useful sequence for delineation of tumor margins and for assessing the extent of tumor, as some lesions are poorly seen on T2-weighted fast spin-echo (FSE) sequences. If margins are not clearly defined on the T1-weighted sequences, the recommendation is to proceed with T2-weighted FSE and contrast-enhanced T1-weighted imaging.[273]

SCCa of the Lip

SCCa of the lip typically arises from the vermillion border and spreads to involve the orbicularis oris muscle and adjacent skin. Small lesions are very difficult to distinguish from normal orbicularis oris muscle fibers. More advanced lesions may extend to directly involve the buccal mucosa and mandible, and rarely the mental nerve, permitting access to the mandibular marrow and potential perineural extension along the inferior alveolar nerve. The presence of osseous involvement classifies a lesion as stage T4 and is a contraindication for treatment with wide local excision.[274] The lymphatic drainage of these tumors is to submental, submandibular, and internal jugular nodes.

SCCa of the Floor of the Mouth

Ninety percent of tumors in this location originate within 2 cm of the anterior midline of the floor of the mouth. Three basic types of information must be provided when evaluating SCCa of the floor of the mouth: (1) the presence and extent of mandibular involvement; (2) the degree of submucosal extension; and (3) the status of regional lymph nodes.[274] Contrast-enhanced CT is the preferred modality for assessment of these lesions due to its availability, its better demonstration of cortical bone invasion, and its superior detection of lymph node metastases.[270] MR imaging, however, is more sensitive than CT for evaluation of bone marrow involvement and perineural tumor spread.[4, 275–277] T1-weighted images, in particular, which normally display mandibular marrow fat as high signal intensity, easily demonstrate marrow replacement, even in the absence of cortical destruction (Figs. 27-86 and 27-87). SCCa of the floor of the mouth is free to spread in virtually any direction. There can be medial spread across the midline, which may occur either directly across the genioglossus muscle and lingual septum or via the potential space between the genioglossus and geniohyoid muscles

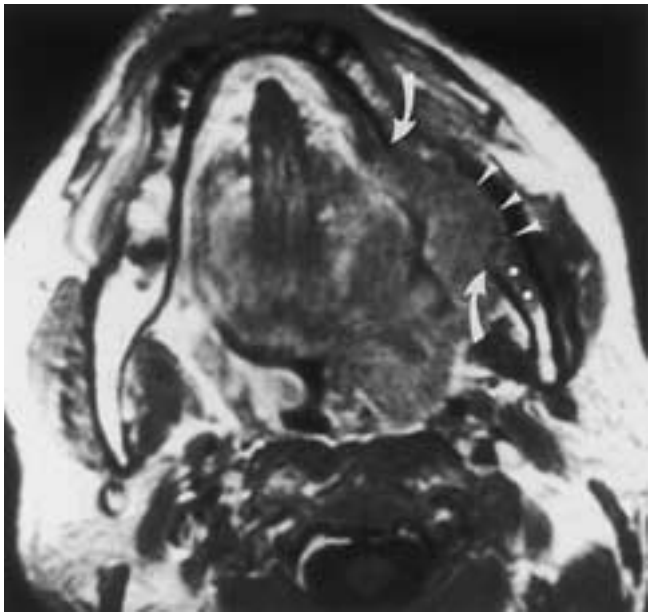

FIGURE 27-86 Squamous cell carcinoma invading the left mandible. Axial T1-weighted image demonstrates a large mass centered in the region on the tongue base and left tonsillar fossa with obvious erosion of a large portion of the lingual surface of the left mandible (*curved white arrows*). The tumor is visualized extending to the buccal cortex of the mandible (*arrowheads*). In addition, however, there is tumor extension into the posterior aspect of the mandible, replacing the normal high-signal fat, in an area where no lingual cortical mandibular destruction is identified (*white dots*).

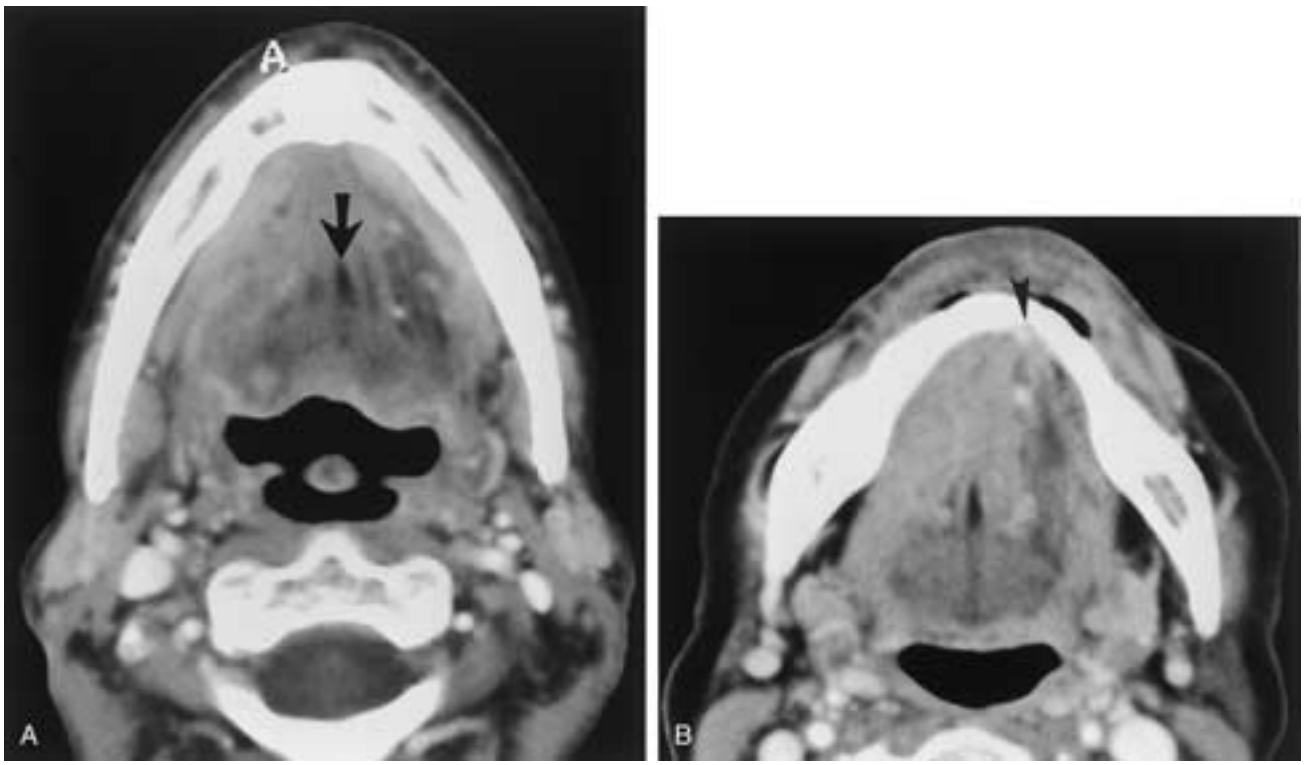
FIGURE 27-87 Marrow invasion in the absence of cortical destruction. Axial T1-weighted (**A**) and T2-weighted (**B**) MR images demonstrate normal high signal intensity marrow on the T1-weighted image in the left aspect of the mandible (*asterisk*) and lack of normal marrow signal in the right mandible (*arrows* in **A**). The pathologic marrow demonstrates high signal intensity on the T2-weighted image (*arrows* in **B**). No evidence of cortical bone erosion is identified. Also note the nearby large myelomatous mass (*M*), as well as the fatty replacement and prolapse of the right hemitongue from denervation atrophy in this patient with myeloma. (Courtesy of Dr. Thomas Underhill.)

(Fig. 27-88). The relationship of the tumor to the lingual septum, as well as to the ipsilateral and contralateral neurovascular bundles, is essential to assess in order to provide appropriate clinical therapeutic counseling. There can be lateral spread, typically contained by the mylohyoid muscle, that involves the periosteum of the mandible. Although the periosteum is an effective barrier against mandibular invasion, in partially or completely edentulous patients (who represent the majority of patients with SCCa), the route of entry is often along the occlusal surface.



VIEW IMAGE

FIGURE 27-88 Squamous cell carcinoma of the floor of the mouth in two different patients. Axial contrast-enhanced CT scans in patients 1 (**A**) and 2 (**B**) demonstrate poorly defined masses in the right floor of the mouth obliterating the right sublingual space fat. In **A** there appears to be involvement of the right genioglossus muscle with midline displacement (*arrow*), while in **B** there is involvement of both genioglossus muscles as well as cortical mandibular erosion (*arrowhead*).

VIEW IMAGE

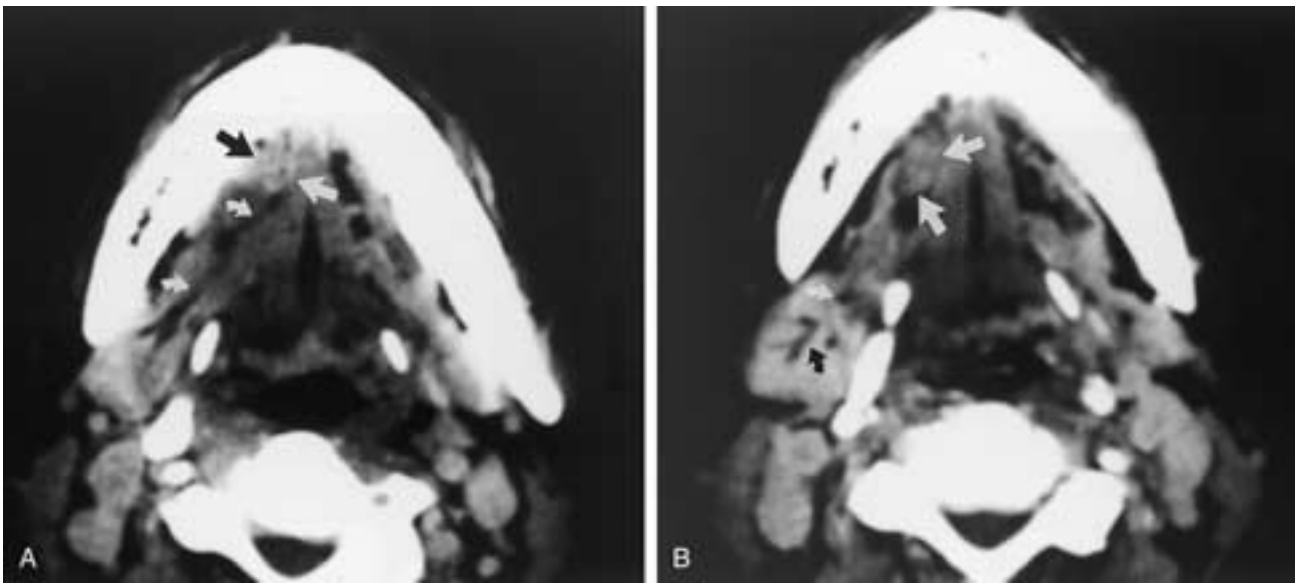
FIGURE 27-89 Small squamous cell carcinoma of the floor of the mouth. Axial contrast-enhanced CT scan reveals a small lesion on the left extending along the mylohyoid muscle (*arrows*). There is subtle asymmetry to the sublingual space fat, and the tumor appears to remain lateral to the left neurovascular structures (*arrowheads*). There are no midline displacements. This lesion was initially overlooked.

Subsequent spread occurs along the horizontal body and ramus of the mandible.[278] Identification of bone erosion immediately places the tumor at the T4 stage. There can be posterior spread along the mylohyoid muscle, usually within the sublingual space (Fig. 27-89), which may extend over the free margin of the mylohyoid muscle into the deep fascial spaces of the upper neck. This spread typically involves the ipsilateral neurovascular bundle. These lesions are T4 lesions that will require mandibulotomy, in addition to a combined transoral and cervical approach.[274] There can be inferior spread along the mylohyoid and hyoglossus muscles within the upper cervical neck to their inferior attachments on the hyoid bone. There can be posteroinferior spread that involves the base of the tongue. Lastly, there can be superior spread that may directly involve the oral tongue.

The ostia of the submandibular ducts may become obstructed by floor-of-the-mouth SCCa, resulting in duct dilatation or obstructive inflammatory enlargement of the submandibular gland (Fig. 27-90). Similarly, obstruction or inflammatory involvement of the sublingual salivary glands may also occur. Encasement of the lingual artery is common, but life-threatening hemorrhage is infrequent. The major lymph node drainage from SCCa of the floor of the mouth is to submental, submandibular, and internal jugular nodes (levels I and II).[2] The depth of tumor invasion in the floor of the mouth is more closely related to the presence of cervical lymph node metastases than is the surface size of the tumor. Thus, careful attention should be given to identify the tumor's depth on imaging.

SCCa of the Oral Tongue

Nearly all SCCa of the oral tongue occur on the ventrolateral surface of the tongue, and most of the lateral lesions arise from the middle and posterior one third of the lateral oral tongue (Fig. 27-91).[279] These tumors typically invade the tongue musculature, spreading easily along the bundles of the intrinsic muscles deeper into the oral tongue or along extrinsic muscles to their sites of attachment (hyoid bone, mandible, styloid process, etc.). These tumors may also extend submucosally to involve the floor of the mouth, tonsils, mandible, and pharyngeal walls (Figs. 27-92 and 27-93).[2] Middle third lateral lesions tend to invade the lateral floor of the mouth and mandible. Posterior third



VIEW IMAGE

FIGURE 27-90 Right squamous cell carcinoma of the floor of the mouth with obstruction of the submandibular gland duct. **A** and **B**, Axial contrast-enhanced CT images demonstrate a tumor in the right floor of the mouth (*straight arrows*), which is best identified by noting the asymmetry of the sublingual space fat between the two sides. The tumor has obstructed the submandibular duct distally, and main duct dilatation (*curved arrows* in **A**) as well as dilated intraglandular ducts (*curved arrows* in **B**) are noted.

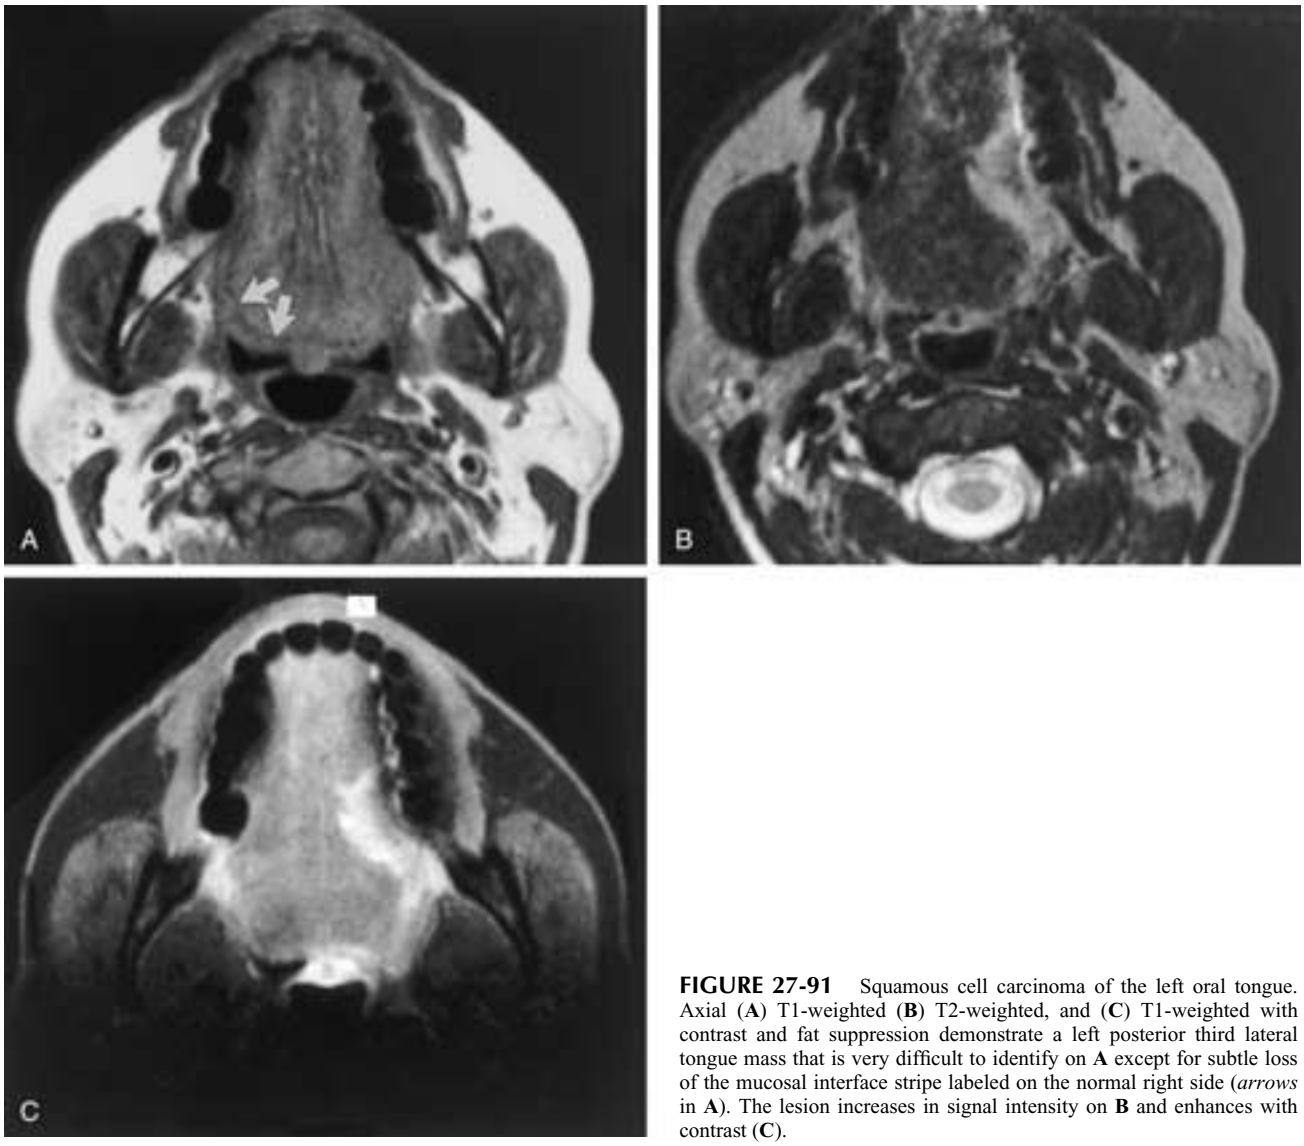

FIGURE 27-91 Squamous cell carcinoma of the left oral tongue. Axial (**A**) T1-weighted (**B**) T2-weighted, and (**C**) T1-weighted with contrast and fat suppression demonstrate a left posterior third lateral tongue mass that is very difficult to identify on **A** except for subtle loss of the mucosal interface stripe labeled on the normal right side (*arrows* in **A**). The lesion increases in signal intensity on **B** and enhances with contrast (**C**).

VIEW IMAGE

lateral lesions grow into the floor of the mouth and glossotonsillar sulcus, the oropharyngeal tonsil, and the underlying deep spaces.[272] Lesions may extend superiorly to the soft palate via the palatoglossus muscle and from the soft palate to the nasopharynx via the veli palatini muscles.[272] When evaluating oral tongue SCCa, it is extremely important to assess the extent of the tumor in relation to the midline (Figs. 27-94 and 27-95). In addition, findings indicative of contralateral lingual neurovascular bundle invasion indicate that total glossectomy is necessary for curative resection or that nonsurgical organ preservation therapy is required. Total glossectomy, although technically possible, is rarely performed because it is poorly tolerated, and demonstration of tumor extension across the midline essentially contraindicates hemiglossectomy. Only recently have partial hemiglossectomies been performed, usually with a free flap reconstruction, and there is promise that these more advanced procedures may be better tolerated by patients. The lymphatic drainage of oral tongue SCCa is primarily to submandibular and internal jugular nodes (levels I and II), often with bilateral involvement.

SCCa of the Gingiva/Buccal Mucosa

Buccal mucosa covers the lips and cheeks and is continuous with the gingival covering on the buccal surface of the maxillary and mandibular alveolar ridges and the retromolar trigone. Overall, SCCa affecting these regions requires an approach to evaluation and management similar to that of carcinomas in the floor of the mouth and oral tongue. Buccal mucosa SCCa most commonly originates along the lateral walls, and lateral submucosal extension along the buccinator muscle to the pterygomandibular raphe with erosion of the underlying bone is the most common method of spread (Figs. 27-96 and 27-97). Mandibular invasion is of special concern for tumors arising in the lower gingiva that may erode the lingual cortex and spread by perineural or intramedullary extension (Figs. 27-98 and 27-99). These lesions mandate extensive resection with segmental mandibulectomy or partial maxillectomy.[279]

SCCa of the Hard Palate

Primary SCCa of the hard palate is rare and usually represents extension from primary gingival SCCa. When

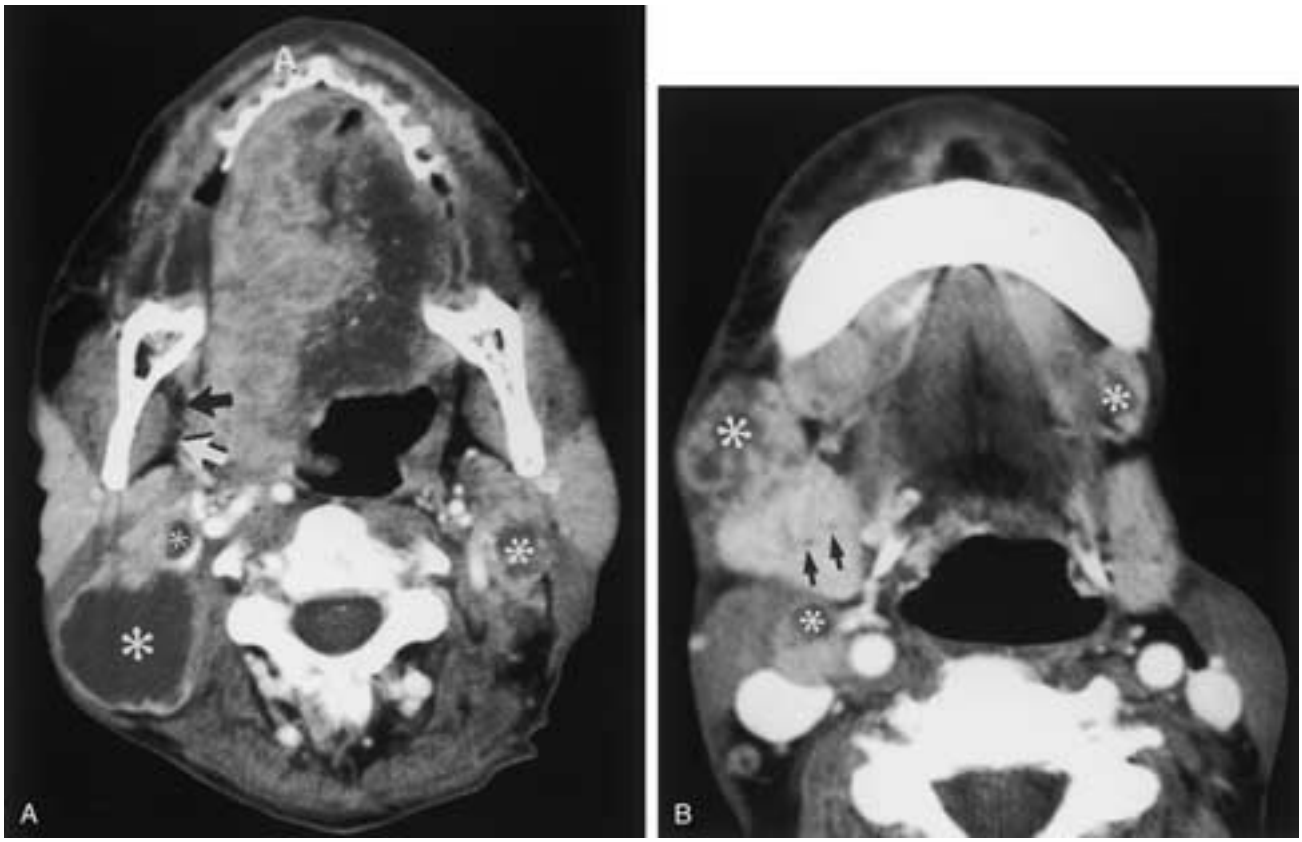
FIGURE 27-92 Squamous cell carcinoma. Axial CT scan with contrast demonstrates a large tumor involving the oral tongue and tongue base extending to involve the oropharynx, tonsillar fossa, carotid, and parapharyngeal spaces. The tumor clearly crosses the midline to involve the left tongue base (*straight arrows*). Extension anteriorly along the mylohyoid muscle and lateral floor of the mouth is present (*curved arrow*). The lingual septum is well visualized (*arrowhead*).

evaluating the uncommon primary SCCa of the hard palate, it is important to assess possible osseous erosion into the floor of the nasal cavity and the maxillary sinus or extension into the soft palate (Fig. 27-100). Perineural tumor extension is of special concern, as tumor may extend along the greater and lesser palatine nerves back to the pterygopalatine fossa and involve the maxillary division of the trigeminal nerve.[274] Perineural tumor extension is best evaluated by MR imaging, especially in the coronal plane.

SCCa of the Retromolar Trigone

Retromolar trigone lesions may extend superiorly deep to the maxillary tuberosity and invade the buccal space fat posterolateral to the maxillary antrum (Fig. 27-101). These lesions may also extend anteriorly along the orbicularis oris and buccinator muscles or posteriorly to involve the superior pharyngeal constrictor muscle, as these muscles arise from the pterygomandibular raphe, which lies beneath the mucosal surface of the retromolar trigone (Fig. 27-102).[274] This spread, not detected clinically, is seen on imaging studies as obliteration of the normal fat planes (Fig. 27-103). The pterygomandibular raphe attaches superiorly to the hamulus of the medial pterygoid plate and inferiorly to the mylohyoid line of the mandible. Involvement of the pterygopalatine fossa, buccal space, and masticator spaces may also occur, allowing invasion of neurovascular bundles and permitting continued cephalad extension to involve the



VIEW IMAGE

FIGURE 27-93 Squamous cell carcinoma. **A** and **B**, Axial contrast-enhanced CT scans demonstrate a large lateral oral tongue tumor that extends to involve the entire right oral tongue and extends posteriorly to the tongue base/oropharynx. The right parapharyngeal space fat is different in density from that on the left, with a ''dirty,'' stranded appearance most likely representing tumor infiltration (*arrows* in **A**). Tumor extension across the midline is obvious in **A**. Large, malignant-appearing, necrotic lymph nodes are present bilaterally (*asterisks*). Obstruction of Wharton's duct is suggested by identification of intraglandular duct dilatation in the right submandibular gland (*arrows* in **B**).

VIEW IMAGE

FIGURE 27-94 Oral tongue squamous cell carcinoma. Contrast-enhanced axial CT scan demonstrates a tumor of the left lateral oral tongue with medial extension across the midline to involve the right oral tongue (*arrows*). Although the tumor is fairly well defined posteriorly, it is poorly defined in its anterior extent and its margins are indistinct.

cavernous sinus via the maxillary and mandibular nerves (Fig. 27-104).[274] Posterior extension may involve the superior pharyngeal constrictor muscle and the tonsil, while posteromedial extension may occur along the pterygomandibular raphe, typically affecting the medial pterygoid muscle; in this case, trismus will almost always be associated. Invasion into the mandibular ramus must also be assessed. Inferomedial spread along the raphe may reach the mylohyoid muscle and the posterior aspect of the floor of the mouth.

Lymphoma

Both Hodgkin's and non-Hodgkin's lymphomas occur in the head and neck region, with lymph node enlargement being the most common presenting symptom for both types of lymphoma. Although Hodgkin's lymphoma tends to be predominantly nodal, with extranodal involvement uncommonly encountered, non-Hodgkin's lymphoma frequently involves extranodal sites.[280, 281]

Although the internal jugular (deep cervical) chain nodes are most often affected, involvement of submandibular nodes occasionally occurs. Involved lymph nodes range in size from 1 cm to several centimeters, and some have been reported to exceed 10 cm.[281] These nodes exhibit striking homogeneity and may manifest peripheral rim enhancement, but central necrosis is distinctly uncommon, reported to occur only after the patient has undergone treatment.[280] It is not possible to differentiate lymph nodes involved by Hodgkin's lymphoma from those affected by non-Hodgkin's lymphoma or metastatic disease solely on the basis of CT or MR imaging. Imaging of lymph nodes is discussed in Chapter 36.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (ACCa) accounts for only 5% of major salivary gland neoplasms, but it comprises more than 25% of the malignancies occurring in the minor salivary glands.[282] More than 1000 minor salivary glands are distributed throughout the upper aerodigestive tract. They are concentrated especially in the buccal, labial, palatal, and lingual regions. Only the gingiva and anterior hard palate have few or none of these glands. ACCa has been reported to involve the minor salivary glands in the maxillary sinuses and nasal cavity, the hard and soft palates, buccal mucosa, floor of the mouth, tongue, lip, and retromolar trigone.[283] These lesions typically occur in the fifth or sixth decade of life, and although some authors report a male predominance, others report a female predominance or no sexual predominance.[284–287]

Three histologic subtypes of ACCa exist: tubular, cribriform, and solid. The degree of cellularity increases from the tubular to the solid form, and in general, the greater the cellularity, the worse the prognosis.[288] Most tumors manifest more than one subtype, making accurate staging difficult. In addition, transformation from one subtype to another suggests that this malignancy may represent a morphologic continuum.

ACCa is characterized by slow, relentless growth and a tendency toward extensive local invasion. A particular feature of this tumor is its propensity for perineural tumor extension. For primary lesions that occur within the oral cavity, this extension mainly affects the maxillary and mandibular branches of the trigeminal nerve due to involvement of the masticator space or the pterygomaxillary fissure. Regional lymph node metastases, however, are uncommon and are primarily associated with more poorly differentiated lesions (solid subtype).[289] ACCa is reported to have a worse prognosis when it involves minor salivary glands compared with major salivary glands.[285, 290] This may be due to the fact that minor salivary gland tumors have a greater opportunity to infiltrate and invade the surrounding soft tissues and bone.[284] In one large series, the median relapse-free interval for patients with major salivary gland ACCa was 83 months compared with 52 months for patients with minor salivary gland tumors.[284] Overall, ACCa carries a grave prognosis, regardless of treatment, as evidenced by the decline in survival of all patients from 58% at 5 years to 16% at 15 years.[291]

On CT and MR imaging, ACCa cannot be distinguished from SCCa or other malignancies on the basis of density or signal intensity (Figs. 27-105 and 27-106). However, signal intensity on T2-weighted images has been shown to correlate well with the degree of tumor cellularity.[292] Lesions with higher signal intensities correspond to tumors with low cellularity and the best prognosis, while tumors with low signal intensity on T2-weighted images have dense cellularity and a poor prognosis (Fig. 27-107).

Among patients with extracranial head and neck malignancies, those with ACCa are at greater risk for perineural tumor extension. Although perineural tumor spread has been reported equally or more often in association with SCCa in some literature, this is most likely a reflection of the more frequent overall occurrence of SCCa.[293–295]

Although CT and MR imaging are reported to be virtually identical in demonstrating perineural tumor below the skull base (provided that direct coronal thin-section CT scans are obtained), MR imaging is superior to CT in demonstrating involvement of the cisternal segments and cavernous sinus portions of the cranial nerves.[295, 296] The topic of perineural

tumor spread is discussed in Chapter 14. In summary, perineural tumor is demonstrated on CT by identifying enlargement of skull base foramina and fissures such as the foramen ovale (V3), the foramen rotundum (V2), and the pterygomaxillary fissure (and pterygopalatine fossa) (V2). Only rarely can a diffusely enlarged nerve be seen on CT. MR imaging may demonstrate increased thickness of the affected nerve(s) (Fig. 27-108) and diffuse or marginal enhancement following administration of contrast. Unfortunately, neither enlargement nor enhancement is pathognomonic for perineural tumor, as it may also be caused by edema, neuritis, primary neural tumor, and, in the cisternal segments, by meningeal inflammatory conditions.[292, 295] False-positive perineural tumor spread in patients with ACCa has been reported, producing an erroneous overestimation of the severity of the disease.[292]

Mucoepidermoid Carcinoma

Mucoepidermoid carcinomas arise from glandular ductal epithelium, and approximately 30% of these tumors arise from the minor salivary glands located primarily in the buccal mucosa and palate. These tumors may be classified as low-, intermediate-, or high-grade lesions. The low-grade lesions tend to behave similarly to benign lesions, with an overall 5-year patient survival rate of 90%. They have a benign imaging appearance with fairly well-delineated, smooth margins. Cystic areas may be present and, rarely, calcifications may be encountered (Figs. 27-109 and 27-110). High-grade lesions are poorly circumscribed, with indistinct infiltrating margins and an overall 5-year patient survival rate of only 42%. These tumors tend to be solid and demonstrate low to intermediate signal intensities on both T1-weighted and T2-weighted MR images (Fig. 27-111).[297] These lesions are discussed further in Chapter 39.

Liposarcoma

Liposarcomas are rare in the extracranial head and neck, although they are common in the retroperitoneum and peripheral soft tissues. Within the oral cavity, these lesions have been reported in the cheek, lip, palate, floor of the mouth, and submental regions.[298, 299] They originate from lipoblasts, within or adjacent to fascia, and do not originate from preexisting lipomas.[1] They are more common in males than in females and occur predominantly in the fourth to sixth decades of life.[298] The histologic tumor type correlates closely with the clinical behavior. The 5-year survival rate for patients with myxoid and well-differentiated tumors is 77% and 85%, respectively, while for round-cell and pleomorphic lesions it is 18% and 21%, respectively.[300]

On CT, liposarcomas are inhomogeneous, demonstrating a combination of fat and soft-tissue elements. The density of the fat is greater than that of subcutaneous fat, and these lesions tend to infiltrate adjacent structures (Fig. 27-112). On MR imaging, liposarcomas appear primarily as fatty lesions but display signal intensities lower than those of subcutaneous fat on short TR sequences.[301]

Rhabdomyosarcoma

Rhabdomyosarcomas are rare malignant mesenchymal tumors, 36% of which involve the head and neck.[302] In spite of a head and neck predilection, rhabdomyosarcoma involving the tongue is rare, representing only 0.34% of cases reported by the Intergroup Rhabdomyosarcoma Studies.[303] These tumors most often involve the base of the

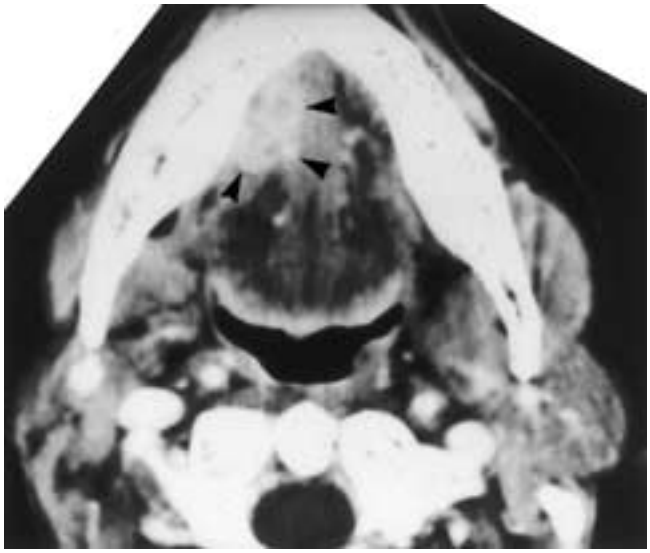
FIGURE 27-105 Adenoid cystic carcinoma of the hard palate. Coronal T1-weighted MR image demonstrates replacement of the normal high signal intensity of the minor salivary gland tissue in the right aspect of the hard palate (*white dot*). Normal salivary glands are identified on the left. This tumor has eroded the inferior aspect of the right maxillary sinus and has an intrasinus component (*arrows*).

tongue but have also been reported within the oral tongue.[304] Oral rhabdomyosarcomas are more common in males and predominate within the first two decades of life.[305]

Rhabdomyosarcomas appear as muscle density masses on CT and as muscle signal intensity masses on MR imaging, although they often have higher T2-weighted signal intensity than normal muscle. These tumors tend to infiltrate the surrounding structures. They may exhibit a variable amount of enhancement following contrast administration.



VIEW IMAGE

FIGURE 27-106 Adenoid cystic carcinoma of the right sublingual gland. Axial contrast-enhanced CT scan reveals an enhancing mass in the anterior aspect of the right tongue obliterating the normally fat-filled right sublingual space (*arrowheads*). On the basis of imaging characteristics, this lesion cannot be distinguished from SCCa originating within the floor of the mouth.

Miscellaneous Malignancies

Cases of other, less common malignancies involving portions of the oral cavity may be found in isolated reports. These include adenocarcinomas (Fig. 27-113), fibrosarcomas, angiosarcomas, myosarcomas, and leiomyosarcomas.[168, 306] Because the buccal space is in intimate contact with the mandible and is fascially contained within the masticator space, malignant lesions involving these regions of the oral cavity not infrequently secondarily involve the mandible and structures within the masticator space. Similarly, lesions of the jaw such as Ewing's sarcoma, chondrosarcoma (Fig. 27-114), osteosarcoma (Figs. 27-115 and 27-116), metastases (Figs. 27-117 and 27-118), and malignant schwannomas of the inferior alveolar nerve (Fig. 27-119), may extend to involve other regions of the oral cavity. Among metastatic lesions, the most common primary tumors in order of frequency are those of the breast, kidney, lung, colon, prostate, and thyroid. Mandibular pathology is discussed in Chapter 17.

Miscellaneous Pathology

Ossification of the Stylohyoid Ligament

The stylohyoid ligament obliquely traverses the neck, extending from the tip of the styloid process of the temporal bone to its attachment on the lesser cornua of the hyoid bone. Medial to the ligament, in close association, are the internal carotid artery, internal jugular vein, and cranial nerves IX to XII. The external carotid artery lies lateral to the ligament.[307] The ligament lies posterior to the tonsillar fossa and lateral to the pharyngeal wall. Ossification of this ligament and elongation of the styloid process have been associated with Eagle's syndrome, with symptoms primarily related to dysphagia (80%), pharyngeal foreign body sensation (55%), and a constantly aching throat (40%).[308] Other symptoms include otalgia, headache, pain on neck rotation, and facial pain.[309] Neck pain along the distribution of the carotid artery has been reported in cases for which surgical or angiographic confirmation of arterial compression by the ossified ligament was demonstrated.[310, 311]

Ossification of the stylohyoid ligament is reported in only 1.4% of the population, with no sex predilection, but very few of these individuals are symptomatic. The syndrome is rare in persons under 30 years of age and is most frequent in the 40- to 80-year-old age range; women tend to be symptomatic more often than men.[312, 313] A case of Eagle's syndrome secondary to fracture of the styloid process has also been reported.[314]

The radiographic identification of stylohyoid ligament ossification is readily apparent on plain radiographs and coronal CT images (Fig. 27-120A,B) and is also identified by observation of persistent small calcifications along the course of the ligament on axial CT images. Reformatted CT is visually impressive (Fig. 27-120C) but not necessary for the diagnosis.

FIGURE 27-108 Adenoid cystic carcinoma of the hard palate. **A** and **B**, Axial and coronal contrast-enhanced CT scans demonstrate a destructive lesion of the right hard palate. There is erosion of the medial wall of the right maxillary sinus with extension of tumor into the sinus, as well as destruction of the posterior aspect of the nasal septum with involvement of the nasal cavity bilaterally. There is widening of the pterygomaxillary fissure on the right (*arrowheads* in **A**) and the inferior orbital fissure (*arrowheads* in **B**), which is highly suggestive of perineural tumor involvement. Involvement of the right masticator space musculature is probable, on the basis of enlargement of the right medial pterygoid muscle, when compared with the normal appearance on the left (*white dots* in **A**). The normal configuration of the parapharyngeal space fat is lost on the right side compared with the normal left. Extension of the tumor along the pharyngeal constrictor muscle on the right is identified by enlargement and poor definition of this muscle. The normal contour of the left pharyngeal constrictor muscle is indicated by the white arrows in **A**. **C**, Coronal T1-weighted MR image demonstrates perineural tumor extension along the right mandibular nerve as it courses through an enlarged right foramen ovale (*white arrows*) into the inferior aspect of the right cavernous sinus.

FIGURE 27-118 Metastatic rectal carcinoma to the left mandible. Axial contrast-enhanced CT scans in (**A**) soft-tissue and (**B**) bone windows reveal a destructive lesion of the left mandible extending through both the lingual and buccal cortices to involve the medial pterygoid and masseter muscles. There is a spiculated appearance that is very similar to that of the osteosarcomas demonstrated in Figures 27-116B and 27-116D. The cortical destruction is best appreciated on the bone window image (*arrows* in **B**), but the spiculation is very faint. (Courtesy of Dr. Deborah Reede.)

Denervation Muscle Atrophy

Motor innervation to the musculature of the oral cavity and masticator space is primarily derived from the mandibular division of the trigeminal nerve (V3), the facial nerve (VII), and the hypoglossal nerve (XII). Damage to these nerves anywhere along their course may lead to denervation and subsequent muscle atrophy with fatty replacement.[315, 316] Various patterns of motor denervation of V3 and XII are presented in Figure 27-121.

The identification of these patterns on CT is based primarily upon the presence of atrophy and fatty replacement of certain muscle groups, which are not appreciated until the chronic stages of denervation occur. On MR imaging, however, abnormalities may be appreciated much earlier in the denervation process if the muscle bundles are of sufficient size.

In the acute/subacute phase of muscle denervation, there is T2 prolongation of denervated muscle secondary to an

increase in extracellular water, which may be associated with increased muscle volume.[34] Abnormal enhancement may also be present secondary to the expanded extracellular space and relatively increased vascularity per cubic millimeter. It is important to become familiar with these acute/subacute changes of denervation (abnormal enhancement and edema-like appearance) because neoplastic and inflammatory processes may have a very similar imaging appearance.[34]

Early chronic denervation changes include visible fatty muscle replacement but no increase in muscle mass, no pathologic enhancement, and no edema-like changes on T2-weighted MR images. Long-standing chronic denervation manifests as substantial muscle volume loss and fatty replacement. In these cases, one must take special care not to diagnose a mass in the larger (normal) muscles. The MR characteristics of denervation are summarized in Table 27-4.

Mandibular Division of the Trigeminal Nerve (V3)

The mandibular division of the trigeminal nerve supplies motor innervation to the muscles of mastication (via the masticator branch), the tensor tympani muscles, and, via the mylohyoid branch of the inferior alveolar nerve, the mylohyoid and anterior belly of the digastric muscles (Fig. 27-122). Proximal injury to the nerve, which is most often affected by perineural spread of tumor or retrogasserian rhizotomy,[294, 295] results in denervation and atrophy of all of these muscles (Figs. 27-123 to 27-125). If the injury occurs more distally, affecting the inferior alveolar nerve after it arises from the main motor trunk, selective atrophy of the mylohyoid and anterior belly of the digastric muscle will result (Fig. 27-126). Identification of denervation atrophy should prompt an exhaustive search along the entire course of the nerve back to the brainstem in an attempt to localize an offending lesion.

Facial Nerve (VII)

The facial nerve supplies motor innervation to a large number of muscles, including the mimetic muscles of facial expression, most of them quite diminutive. For the purposes of this discussion, only those muscles that may be identified on cross-sectional imaging are of interest and include the zygomaticus major, buccinator, and platysma muscles (Fig. 27-127). Acute/subacute and early chronic changes of denervation are very difficult to identify within these muscles due to their small size, and it is not until substantial atrophy and fatty infiltration occur that atrophic changes can be identified. Fibers of the buccinator are easily recognized on MR images that demonstrate the parotid gland duct as it pierces the muscle. The widths of the muscles on the two sides can readily be compared and atrophic changes appreciated (Fig. 27-128). Atrophic changes of the zygomaticus muscle bundle may also be identified, but one must be certain that the patient is centered and not rotated on the images. Platysma atrophy usually manifests as failure to identify muscle fibers on the affected side.

The facial nerve is often damaged during parotid gland surgery but is also affected by neoplasms. As with the mandibular nerve, the entire course of the facial nerve must be examined when denervation atrophy is identified.

Hypoglossal Nerve (XII)

The hypoglossal nerve supplies motor innervation to intrinsic and extrinsic tongue musculature from its nucleus within the medulla (Fig. 27-129). Chronic atrophic changes are easily identified on both CT and MR imaging, but as the tongue represents a large muscle bundle, acute/subacute changes may also be identified on MR imaging. Acute denervation atrophy of the hypoglossal nerve produces initial enlargement and enhancement of the affected hemitongue, as described previously, and if imaging is performed at this time, the affected side of the tongue may be mistakenly diagnosed as harboring a mass (Figs. 27-130

Text continued on page 1456

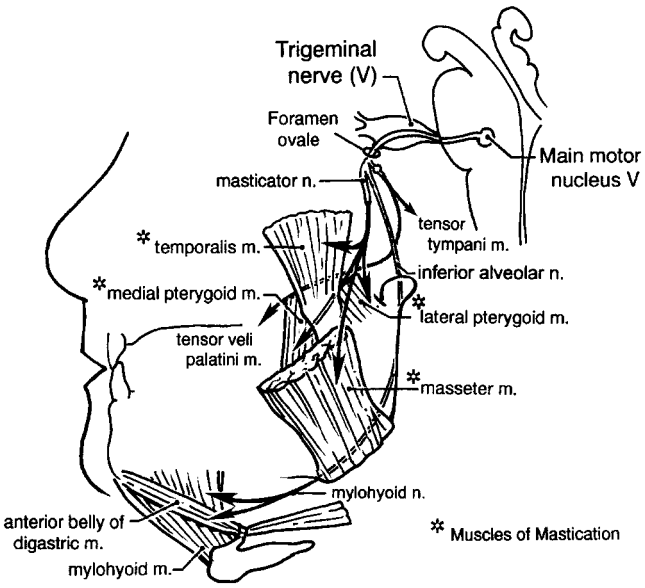

FIGURE 27-122 Motor fibers of the mandibular division of the trigeminal nerve (V3). The motor nucleus of the trigeminal nerve is located in the middle pons. The nerve root exits the brainstem at the lateral pons, courses through the prepontine cistern (preganglionic segment), and passes into the gasserian ganglion within Meckel's cave, just lateral to the cavernous sinus. The postganglionic segment trifurcates just distal to the ganglion, and V3 passes inferiorly to exit the skull base via the foramen ovale. V3 enters the masticator space; the motor component divides into two branches: the masticator nerve and the mylohyoid nerve. The masticator nerve supplies the muscles of mastication, and the mylohyoid nerve supplies the anterior belly of the digastric and the mylohyoid muscles.

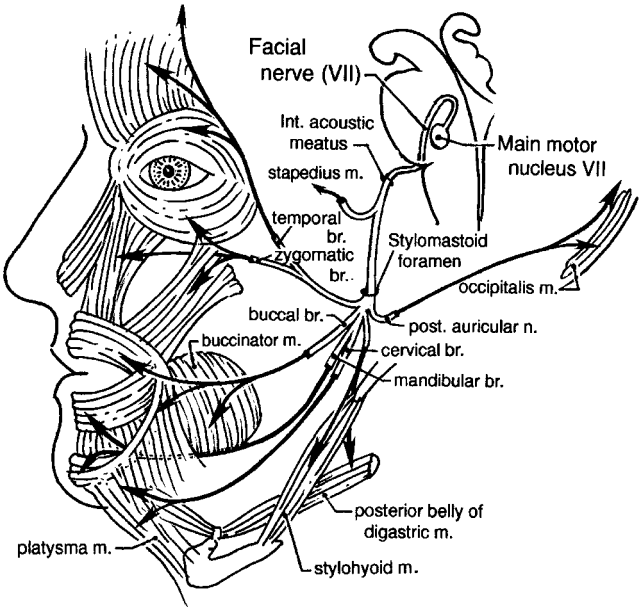

FIGURE 27-127 The facial nerve nucleus is at the level of the pons. This complex nerve provides small branches to the posterior belly of the digastric and stylohyoid muscles just after it exits the skull base through the stylomastoid foramen. Within the substance of the parotid gland, the facial nerve divides into its five terminal branches supplying motor innervation to the small muscles of facial expression, as well as to the buccinator and platysma muscles.

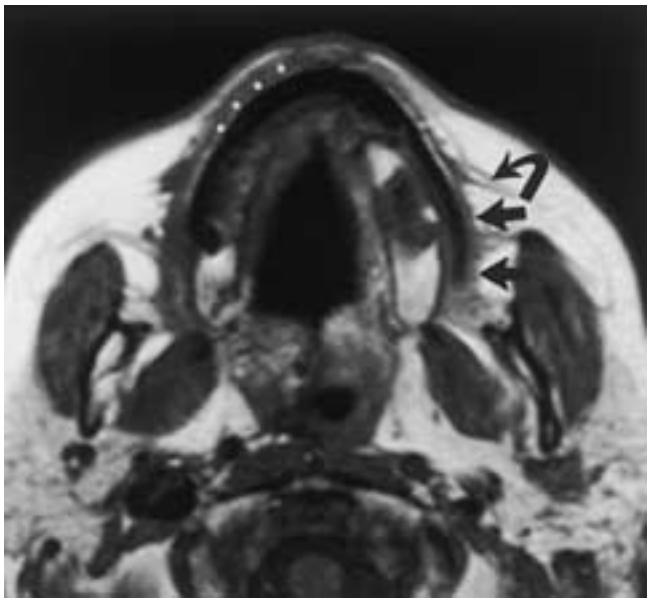

FIGURE 27-128 Early chronic facial nerve denervation in a woman who had undergone left parotid gland surgery. Axial T1-weighted MR image reveals fatty replacement and volume loss involving the left buccinator (*straight arrows*) and zygomaticus (*curved arrow*) muscles. Also note the involvement of other small mimetic facial muscles on the left compared to the normal muscle mass on the right (*dots*).

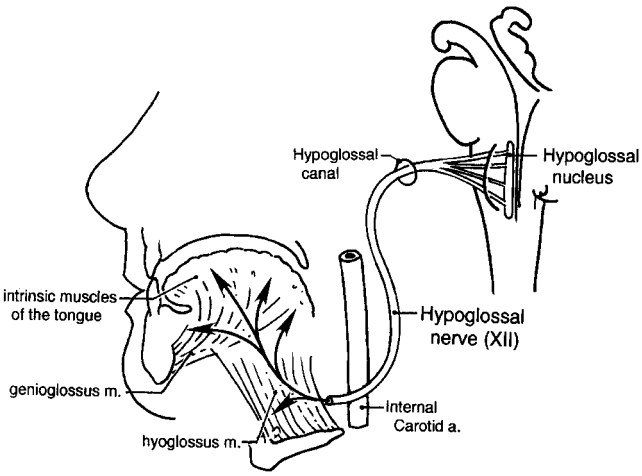

FIGURE 27-129 In this diagram, the hypoglossal nuclei are situated in the medulla, just deep to the floor of the fourth ventricle. Multiple XII nerve rootlets exit the medulla at the preolivary sulcus, in proximity to the vertebral artery, and cross the premedullary cistern to enter the hypoglossal canal. After emerging from the hypoglossal canal, nerve XII passes into the carotid space and loops caudally to the level of the hyoid bone. The nerve then courses upward to the sublingual space, where it ramifies to supply motor branches to the intrinsic and extrinsic muscles of the tongue.

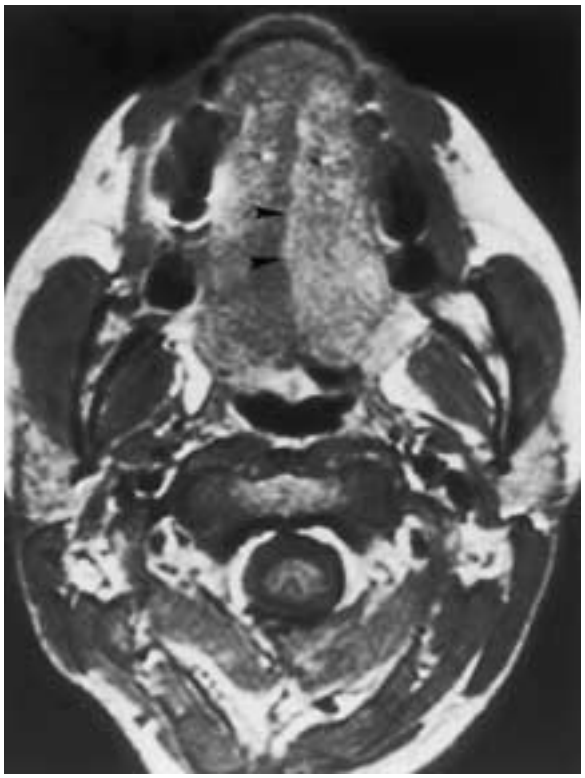

FIGURE 27-130 Acute hypoglossal nerve denervation. Axial T1-weighted MR image in a 17-year-old female after left tonsillectomy 2 weeks earlier. The examination reveals the earliest changes of denervation atrophy of the left hemitongue, which, because it is imaged relatively acutely, demonstrates a positive mass effect (*arrowheads*). Early fatty infiltration is identified by high-signal replacement of the intrinsic tongue musculature. (From Smoker WRK. The hypoglossal nerve. Neuroimag Clin North Am 1993;3:193–206.)

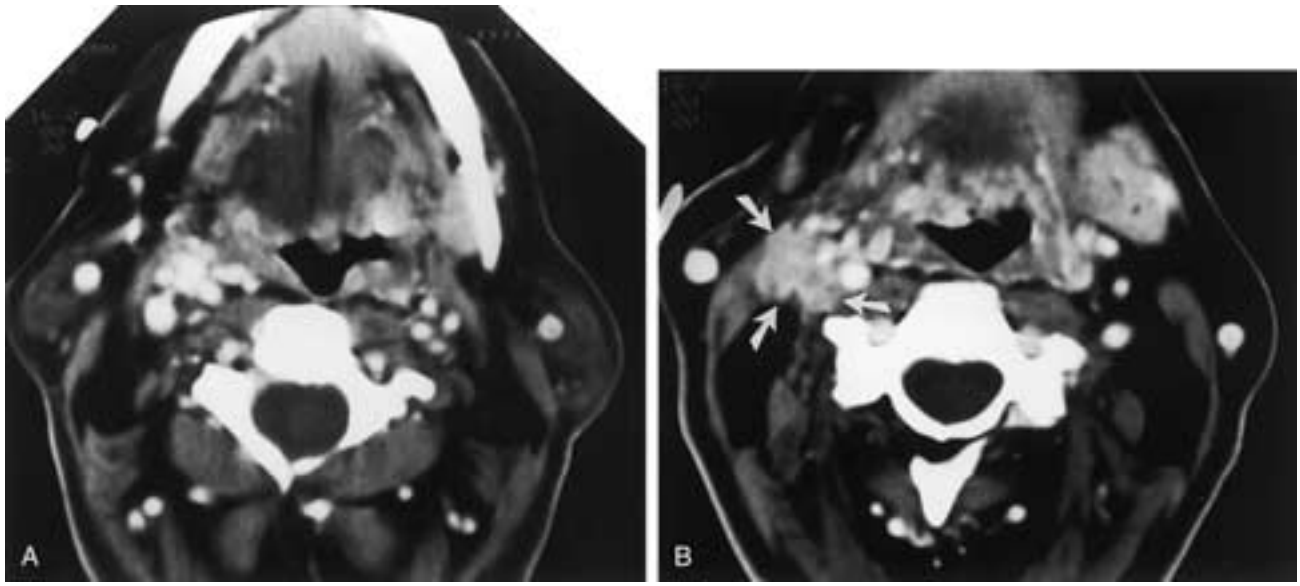
VIEW IMAGE

FIGURE 27-131 Acute hypoglossal nerve denervation. (**A**) Axial T2-weighted and (**B**) axial T1-weighted images with contrast enhancement and fat suppression reveal edema-like increased signal intensity in the right hemitongue on **A** that demonstrates enhancement (**B**). Note the protrusion of the hemitongue across the midline and posteriorly into the oropharynx (*arrows*).

and 27-131).[34] The first clinical sign of peripheral XII palsy is deviation of the tongue toward the side of pathology, primarily the result of paralysis of the genioglossus muscle, which controls protrusion of the tongue. More often, however, imaging is not performed until the paralysis has become permanent, at which time the affected hemitongue is replaced by variable amounts of fat (Fig. 27-132). With long-standing denervation, the muscle bundles will no longer be recognizable and only the arteries and veins remain intact. At this time, the atrophic hemitongue prolapses back into the oropharynx (Figs. 27-133 and 27-134). As with all denervated muscles, the entire course of the nerve must be evaluated in the search for an offending lesion.



VIEW IMAGE

FIGURE 27-132 Early chronic hypoglossal nerve denervation. **A** and **B**, Axial CT scans in a 46-year-old woman 8 years after mastectomy for breast carcinoma who now presents with right cranial nerve XII palsy. At the level of the mandible (**A**), fatty replacement and loss of muscle fibers involving the intrinsic musculature and genioglossus muscles of the right hemitongue are identified by its lower density compared with the left hemitongue. On a more inferior plane (**B**) an extranodal mass is visible adjacent to the right carotid sheath (*arrows*), which proved to be metastatic breast carcinoma. This case highlights the importance of imaging the most inferior loop of the hypoglossal nerve, inferior to the mandible, so as to visualize nerve XII fibers coursing in the low oropharyngeal carotid space.

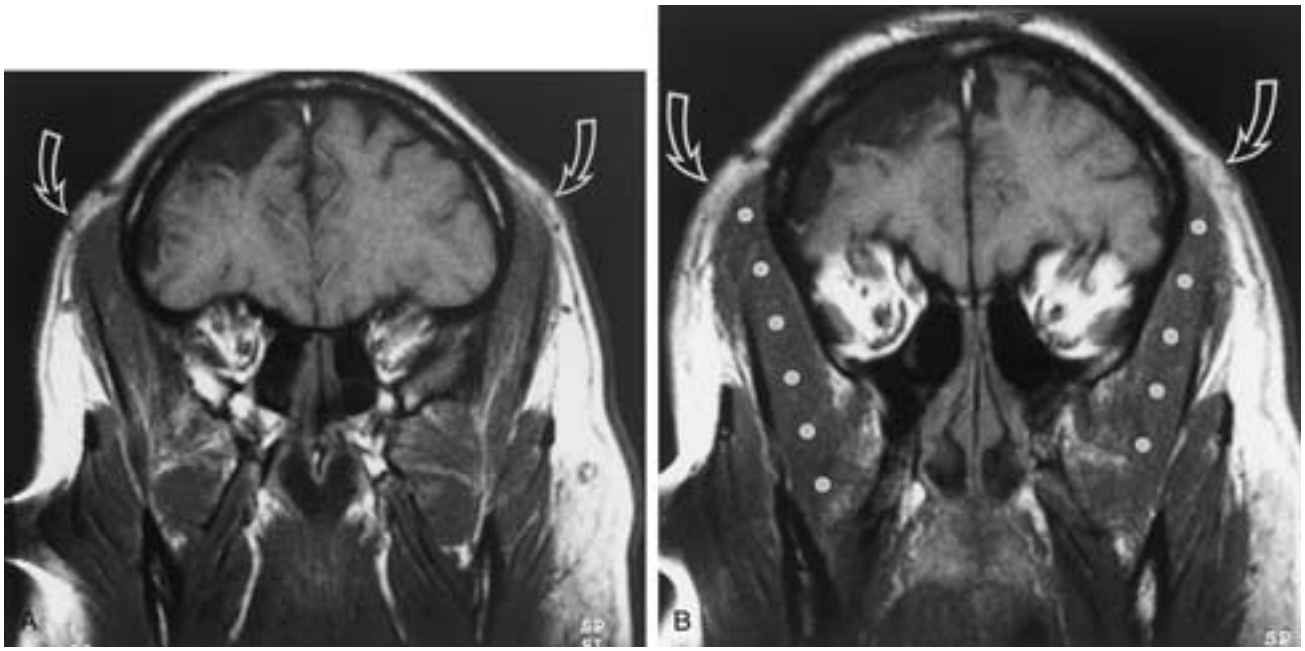
FIGURE 27-135 Benign masseteric hypertrophy. (**A**) Axial CT scan without contrast enhancement and (**B**) T1-weighted MR image reveal marked bilateral enlargement of the masseter muscles, which are otherwise normal in density/signal intensity and contour (*arrows*). (Courtesy of Dr. Deborah Reede.)

Benign Masseteric Hypertrophy

Benign masseteric hypertrophy (BMH) refers to idiopathic enlargement of the masseter muscle. Although uncommon, this condition is important because it must be considered in the differential diagnosis of masses in the parotid region.[22] Males are affected twice as often as females, and approximately 50% of the cases are bilateral. The etiology of BMH is uncertain, although a variety of theories have been proposed. Both familial and acquired forms are likely, with the acquired form most often associated with dental malocclusion or bruxism (teeth grinding).[24] CT and MR imaging demonstrate enlargement of the involved muscle(s) with preservation of muscle margins and surrounding fascial planes; otherwise, the hypertrophic muscle(s) look the same as the noninvolved normal muscles (Fig. 27-135). In some patients, an area of hyperostosis is present at the mandibular insertion of the masseter muscle, probably representing a secondary manifestation of muscle hypertrophy. In addition to isolated BMH, diffuse hypertrophy involving all muscles of mastication in patients with bruxism may occur (Fig. 27-136).[24, 317]



VIEW IMAGE

FIGURE 27-136 Hypertrophy of all muscles of mastication. **A** and **B**, Coronal T1-weighted MR images demonstrate marked enlargement of all muscles of mastication bilaterally. Note especially the temporalis muscle hypertrophy (*dots* in **B**) in the suprazygomatic masticator spaces, which causes the contour of the overlying scalp to bulge (*arrows*).

Macroglossia

Macroglossia, or tongue enlargement, is for the most part a clinical diagnosis. In addition to occurring in any number of tumoral conditions, macroglossia may occur in a variety of congenital, endocrine, and metabolic conditions (Table 27-5). From their study of 40 normal persons and 12 patients with systemic primary amyloidosis involving the tongue, Larsson et al. suggested that macroglossia can be suspected if (1) the base of the tongue is more than 50 mm in the transverse diameter, (2) the genioglossus muscle is more than 11 mm in the transverse diameter, (3) the surface of the tongue base has a midline cleft, and (4) despite being normal in size, the submandibular glands are displaced laterally, producing an outward bulging of the overlying platysma muscles.[10]

With regard to amyloidosis of the tongue, scattered CT reports indicate symmetric enlargement of both the extrinsic and intrinsic tongue musculature. Obliteration of the normal fascial planes, caused by increased muscle bulk, is typically present, without identification of any focal mass.[10, 12] This is in sharp contrast to tumors, which, until well advanced, usually present as focal masses that do not typically involve both the intrinsic and extrinsic tongue muscles but do displace the normal fascial planes. In amyloidosis the abnormally enlarged, infiltrated musculature does not exhibit pathologic enhancement. Usually the T1-weighted and T2-weighted signal intensities are similar to those of normal skeletal muscle.

INTRODUCTION

Behind the oral cavity, and extending from the skull base to the level of the caudal cricoid cartilage, is the mucosa-lined musculomembranous tube known as the *pharynx*.[1, 2] Historically, the pharynx has been subdivided into three sections: the nasopharynx, which extends from the skull base to the level of the hard palate; the oropharynx, which extends from the level of the hard palate to the level of the hyoid bone; and the hypopharynx, which extends from the level of the hyoid bone to the caudal margin of the cricoid cartilage or the top of the cricopharyngeus.

GENERAL ANATOMY

There are three overlapping constrictor muscles that comprise the primary pharyngeal musculature.[1] All of these muscles insert posteriorly in the midline on a median raphe that is attached to the skull base at the pharyngeal tubercle.

Copyright © 2003, Mosby, Inc. All rights reserved.

The superior constrictor muscle has its origin from the lower third of the posterior edge of the medial pterygoid plate, the pterygomandibular raphe, the alveolar process of the mandible, and the lateral aspect of the tongue. The middle constrictor muscle has its origin along the stylohyoid ligament and the greater and lesser cornua of the hyoid bone. The inferior constrictor muscle has its origin from the oblique line of the thyroid cartilage, the lateral cricoid cartilage, and the posterior border of the cricothyroid muscle. Structurally, the inferior constrictor muscle encircles the lower middle constrictor muscle, which in turn encircles the lower superior constrictor muscle.

The cricopharyngeus sphincter muscle is composed of parallel, nonraphed horizontal fibers that extend from one side of the cricoid cartilage to the other. This sphincter separates the hypopharynx from the cervical esophagus.[1] As a functioning unit, the pharyngeal constrictor muscles increase intrapharyngeal pressure as they contract in an organized, peristaltic manner from superiorly to inferiorly. There are no major pharyngeal dilator muscles, and the pharynx is primarily passively dilated by increasing intrapharyngeal pressure. The pharyngeal constrictor muscles are supplied by the pharyngeal plexus, formed primarily by branches of cranial nerves IX and X, with branches from cranial nerve XI and branches from the sympathetic plexus.

The salpingopharyngeus, stylopharyngeus, palatopharyngeus, and tensor and levator veli palatini muscles also contribute to the pharynx and its function. The salpingopharyngeus extends from the eustachian tube cartilage to interdigitate with posterior fascicles of the palatopharyngeus. This muscle is supplied by the pharyngeal plexus, and helps raise the pharynx and open the eustachian tube orifice during swallowing.

The stylopharyngeus extends from the styloid process caudally, passing between the external and internal carotid arteries, to insert on the superior and posterior borders of the thyroid cartilage, with some fibers intermingling with the constrictor muscles. This muscle raises, and to a minimal degree dilates, the pharynx. It is supplied by cranial nerve IX.

The palatopharyngeus extends from the soft palate and the pharyngeal wall to the posterior border of the thyroid cartilage, forming the substance of the posterior tonsillar pillar. This muscle narrows the oropharyngeal isthmus, elevates the pharynx, and helps close off the nasopharynx. It is supplied by the pharyngeal plexus.

The tensor veli palatini extends from the scaphoid fossa, sphenoid spine, and lateral side of the eustachian tube, around the hamulus of the pterygoid process, to the soft palate and part of the palatine bone. The tensor runs primarily outside of the pharynx and is considered part of the deglutitory musculature. It is innervated by the third division of the trigeminal nerve.

The levator veli palatini muscle has its origin from the undersurface of the petrous portion of the temporal bone and the medial side of the eustachian tube. It runs through the sinus of Morgagni, along the upper posterior edge of the medial pterygoid plate, and caudally within the pharynx to insert in the soft palate. As such, it is considered a pharyngeal muscle and it is innervated by the pharyngeal plexus.

The levator veli palatini and tensor velli palatini muscles function together to elevate and firm the soft palate, effectively closing off the nasopharynx during swallowing. These palatini muscle and the salpingopharyngeus also function together to maximize the patency of the eustachian tube orifice during swallowing.

The arterial supply of the pharynx is from the major branches of the external carotid artery, including the ascending pharyngeal artery, tonsillar branches of the facial artery, and palatine branches of the maxillary artery.[1, 2] The primary venous drainage is via the pharyngeal veins, which communicate with the pharyngeal plexus located in the lateral aspect of the pterygopalatine fossa and which then drain inferiorly into the internal jugular vein.

EMBRYOLOGY

The embryology of the branchial apparatus is discussed in detail in Chapter 33. Briefly, those derivatives that pertain to the pharynx include the muscles of mastication, the tensor veli palatini muscle, and the anterior belly of the digastric muscle, all of which come from the first branchial arch. All of these muscles are innervated by the mandibular division of the trigeminal nerve. The first pharyngeal pouch is the precursor to the eustachian tube.[3]

The ventral second branchial arch forms the lesser cornu and superior portion of the hyoid bone, while the dorsal second arch gives rise to the styloid process and the stylohyoid ligament. The muscles derived from the second arch mesoderm, and thus innervated by the facial nerve, include the posterior belly of the digastric and the stylohyoid muscle.[3] The ventral portion of the second pharyngeal pouch is largely obliterated by the development of the palatine tonsil. The dorsal portion of the second pouch gives rise to the tonsillar fossa. The endoderm proliferates and forms the surface epithelium and the lining of the palatine tonsillar crypts. The second arch mesenchyme forms the lymphatic tissue of the palatine tonsils.

The third branchial arch forms the lower body and greater cornu of the hyoid bone. The third branchial arch forms the stylopharyngeus, which is supplied by the glossopharyngeal nerve. Some authors claim that the palatopharyngeus muscle is also a third arch derivitive.[4] The mucosa covering the posterior third of the tongue (base of the tongue) is a derivative of the third arch.

SPECIFIC ANATOMY

Nasopharynx

The nasopharynx is an epithelium-lined cavity situated in the uppermost aerodigestive tract. It is approximately 2 cm in anteroposterior diameter and 4 cm in height. The roof is downward sloping and is formed from cranially to caudally by the basisphenoid, the basiocciput, and the anterior aspect of the first two cervical vertebrae.[1,5] The inferior margin of the nasopharynx is the level of the hard palate and Passavant's muscle. This muscle is composed of fibers that arise laterally from the palatopharyngeus muscle and the lateral aspect of the posterior border of the hard palate. The

Copyright © 2003, Mosby, Inc. All rights reserved.

fibers encircle the pharynx inside the superior constrictor muscle. When they contract they raise a ridge, Passavant's ridge, which opposes the soft palate when it is elevated. The ridge meeting the elevating soft palate closes off the nasopharynx during swallowing.

The lateral nasopharyngeal walls are formed and supported by the margins of the superior constrictor muscle and the pharyngobasilar fascia. The nasopharynx is fairly rigid, having its shape maintained by the strong pharyngobasilar fascia. This fascia is considered the cranial extension of the upper edge of the superior pharyngeal muscle and extends from this muscle to the skull base. Anteriorly, the nasopharynx is in direct continuity with the nasal cavity via the posterior choanae.[1, 5]

The nasopharynx communicates with the middle ear cavity via the eustachian tubes. As mentioned, these tubes gain access to the nasopharynx through the sinus of Morgagni, a defect in the anterior portion of the pharyngobasilar fascia, which is above the superior pharyngeal constrictor muscle and along the upper posterior border of the medial pterygoid plate (Figs. 28-1 and 28-2). The sinus of Morgagni is also the route of entry into the pharynx for the levator velli palatini muscle, and this pathway may provide access for advanced nasopharyngeal cancer to spread to the parapharyngeal region and central skull base.[5, 6]

The opening of each eustachian tube is located along the upper posterolateral wall of the nasopharynx, and with the cartilaginous eustachian tube, the levator veli palatini muscle, and the overlying mucosa, it forms the torus tubarius. The opening of the eustachian tube is about 1 cm behind and slightly below the posterior end of the inferior turbinate. Because of their location, the eustachian tubes are prone to obstruction by nasopharyngeal masses. It is estimated that such obstruction, which results in serous otitis, occurs in 50% of patients with a nasopharyngeal mass.[5–7]

Located just behind and above the torus tubarius is the fossa of Rosenmüller, a mucosa-lined recess that is the most cranial and superior aspect of the lateral recess of the nasopharynx. This fossa lies immediately lateral to the flexor muscles of the neck, the longus capitus and coli muscles (Fig. 28-3), and is a common site of origin of nasopharyngeal cancer.[8, 9] When tumors arise in this fossa, they are often clinically occult.[5, 6] Mucosal folds are also present in the nasopharynx, covering the salpingopharyngeus and levator veli palatini muscles. During a normal swallow, the palatini muscles and the salpingopharyngeus muscle pull the margins of the cartilaginous end of the eustachian tube in opposing directions, thereby maximizing the opening of this tube and allowing equalization of pressure between the pharynx and the middle ear.

The mucosa of the nasopharynx is composed of both stratified squamous and columnar epithelium. The latter predominates during the first 10 years of life, whereas stratified squamous epithelium becomes more common with advancing age. The adenoids, or pharyngeal tonsils, are lymphatic tissue located in the midline roof of the nasopharynx. Prominent adenoids are typically present in children, and if such adenoids are not identified, the patient is either in an immune deficiency state or has an immune deficiency syndrome. The maximal size of the adenoids occurs at about 5 years of age; around the time of puberty, gradual adenoidal involution normally begins. The majority of individuals have lost most of this adenoidal tissue by 30 years of age.[8, 10] Nonetheless, normal adenoidal tissue may occasionally be seen in adults in their fourth, fifth, and even sixth decade of life. After the first decade of life, it is unusual for the adenoidal mass to extend up to the posterior margin of the medial pterygoid plate. If such a nasopharyngeal mass is seen in an older patient, clinical correlation should be sought.

The visceral (buccopharyngeal) fascia surrounds the nasopharyngeal mucosa and the constrictor muscles. This

fascia separates the nasopharynx from the deep fascial spaces and is thought to be a barrier to deep spread of infection and early malignancy (see also Chapter 34) (Fig. 28-4).[5–8, 11] An extensive lymphatic plexus drains the nasopharynx, and this explains the high incidence of cervical nodal metastases associated with nasopharyngeal carcinomas.[5, 7, 12] Primary nodal drainage is to the retropharyngeal nodes. However, the lymphatic pathways to these

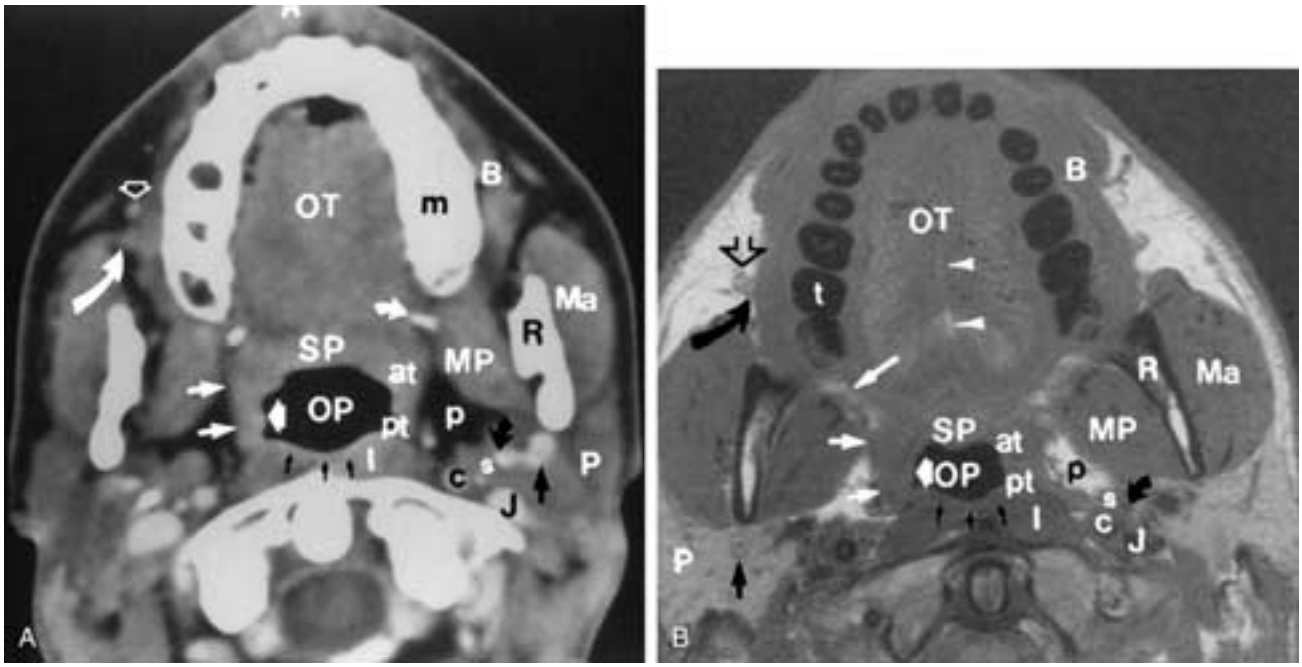
nodes are thought to become obliterated by adulthood secondary to the numerous pharyngeal infections that occur in childhood. As such, nasopharyngeal cancers often drain to the second-order nodes in levels II, III, and occasionally in level V.[5, 12]

Oropharynx

The oropharynx is the region of the pharynx posterior to the oral cavity (see Chapter 27) and includes the posterior one third of the tongue (tongue base), the palatine tonsils, the soft palate, and the oropharyngeal mucosa and constrictor muscles. The posterior oropharyngeal wall is related to the second and third cervical vertebrae. Laterally are two faucial arches. The anterior arch is formed by mucosa over the palatoglossus muscle, and the posterior arch is formed by mucosa over the palatopharyngeus muscle. Between these arches is the tonsillar fossa containing the palatine tonsil (Figs. 28-5 and 28-6). The visceral fascia surrounding the mucosa and musculature of the pharynx often acts as a barrier to contain tumor. However, if this fascia is violated, tumor can invade posteriorly into the longus capitis and colli muscles and the vertebrae.[13] Lateral tumor extension on either side is into the lower parapharyngeal space. The palatine tonsils rapidly increase in size over the first 5 to 6 years of life, and reach maximal size at puberty (20–25 mm in vertical diameter and 10–15 mm in transverse diameter).



VIEW IMAGE

FIGURE 28-6 Axial CT scan demonstrates the characteristic appearance of benign tonsillar calcifications (*curved arrows*).

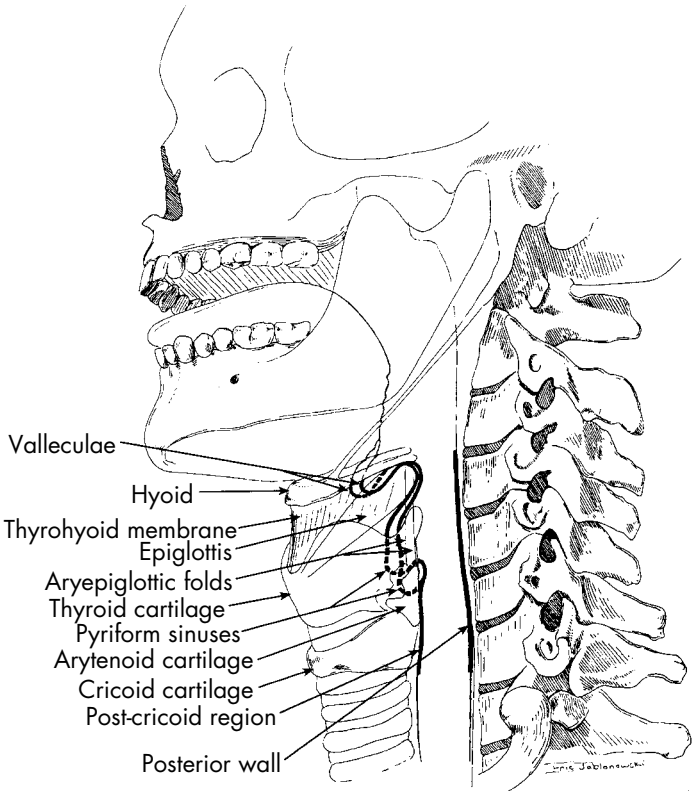
The lingual tonsil, which can be quite variable in size, lies at the base of the tongue. It is usually more prominent laterally, often with a midline groove. Although this tonsillar tissue can normally extend down to the anterior wall of the vallecula, it will not extend into the floor or posterior vallecular wall. Thus, any contiguous mass with the lingual tonsil that does extend into the vallecular floor or posterior wall should be considered a tumor until proven otherwise.

The major arterial supply to the oropharynx is from the tonsillar branch of the facial artery, the ascending pharyngeal artery, the dorsal lingual arteries, and the internal maxillary and facial arteries. The majority of venous drainage is through the peritonsillar veins, which pierce the constrictor musculature and drain into the common facial vein and the pharyngeal plexus.[1, 2] The primary lymphatic drainage is to level II and III nodes, the retropharyngeal nodes, and less often to level V nodes. The palatine tonsil can also drain to the parotid nodes (see Chapter 36).[12]

Hypopharynx

The hypopharynx, or laryngopharynx, is the most caudal portion of the pharynx that extends from the level of the hyoid bone to the cricopharyngeus.[14, 15] On imaging, this caudal margin can be approximated by the lower level of the cricoid cartilage. Below this level, the gullet becomes the cervical esophagus (Fig. 28-7). Most authors divide the hypopharynx into the following three regions: the pyriform sinuses, the posterior wall, and the postcricoid region (Fig. 28-7).[14–16] Some authors also refer to a fourth or ''marginal'' area, the hypopharyngeal (lateral) surface of each aryepiglottic fold (Fig. 28-7).[17]

The pyriform (pear-shaped) sinus is an anterolateral recess of the hypopharynx situated on either side of the pharynx between the inner surface of the thyrohyoid membrane and thyroid cartilage and the lateral surface of the aryepiglottic fold. The anterior pyriform sinus mucosa abuts on the posterior paraglottic space of the larynx.[14] The most caudal portion, or apex, of each pyriform sinus lies at the level of the true vocal cord (Figs. 28-8 and 28-9). As mentioned, the lateral wall of the pyriform sinus is formed above by the thyrohyoid membrane and below by the thyroid cartilage. These two areas have been referred to



VIEW IMAGE

respectively as the membranous and cartilaginous portions of this lateral pyriform sinus wall.[14–16]

The medial wall of the pyriform sinus is formed by the lateral surface of the aryepiglottic fold and is often considered a marginal zone. Although the aryepiglottic fold is part of the supraglottic larynx, it can also be considered part of the hypopharynx. An aryepiglottic fold tumor confined to the laryngeal surface behaves clinically like a supraglottic tumor. However, a tumor involving the lateral wall of the aryepiglottic fold usually behaves more aggressively, more consistent with the behavior of hypopharyngeal tumors.

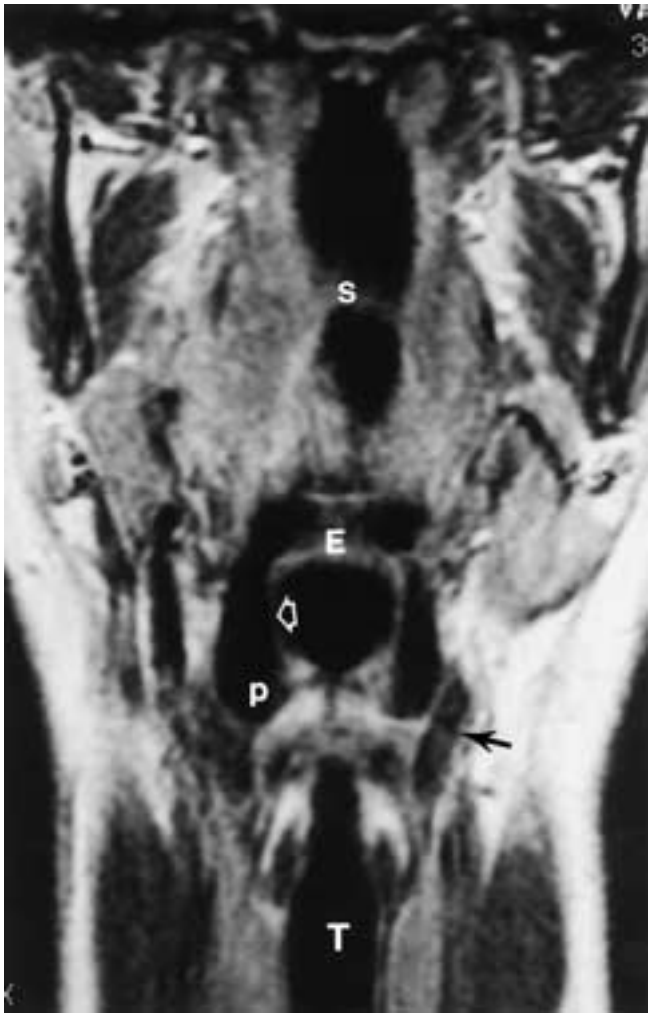
The posterior wall of the hypopharynx is the inferior continuation of the posterior wall of the oropharynx. The hypopharynx is considered to start at the level of the hyoid bone (and valleculae) (Fig. 28-10). Caudally, the posterior and lateral walls of the hypopharynx merge with the cricopharyngeus, which in turn merges with the cervical esophagus. The visceral fascia surrounds the inferior pharyngeal constrictor muscles, and the retropharyngeal space lies behind the posterior pharyngeal wall (see Chapter 36).

The postcricoid region is the anterior wall of the lower hypopharynx. This area is the interface between the hypopharynx and the anteriorly located larynx (Fig. 28-11).

Copyright © 2003, Mosby, Inc. All rights reserved.

The postcricoid portion of the hypopharynx extends from the level of the cricoarytenoid joints down to the lower edge of the cricoid cartilage. Thus, the postcricoid regions abuts the dorsal surface of the cricoid lamina.[14–16]

The inferior pharyngeal constrictor muscle has two components. The upper fibers arise from the posterior midline pharyngeal raphe and insert on the thyroid cartilage. These fibers are obliquely oriented, being highest in the posterior midline.[18] The inferior pharyngeal oblique fibers overlap and interdigitate with the oblique muscle fibers of the middle pharyngeal constrictor muscle.[19] The lowermost portion of the inferior pharyngeal constrictor, the cricopharyngeus, is composed of horizontally oriented, parallel, nonraphed muscle fibers that arise from either side of the cricoid cartilage. These fibers become continuous with the circular muscles of the cervical esophagus.[18, 19] Between the upper border of the cricopharyngeus and the lowermost margin of the oblique fibers of the inferior pharyngeal constrictor muscle on either side of the raphe is a small triangular, mucosa-covered space called Killian's dehiscence. It is through this area that Zenker's diverticulum arises.



VIEW IMAGE

FIGURE 28-9 Coronal T1-weighted MR image after gadolinium administration shows the pyriform sinuses (*p*), epiglottis (*E*), aryepiglottic folds (*open arrow*), thyroid cartilage (*solid arrow*), soft palate (*s*), and trachea (*T*).

The superior, middle, and inferior pharyngeal constrictors contract in a coordinated peristaltic manner with each swallow. This contraction increases intrapharyngeal pressure, creating a pressure head that assists in moving a bolus from the hypopharynx into the cervical esophagus. The cricopharyngeus, or superior esophageal sphincter, is normally closed in its resting state. In response to a minimum specific volume and pressure in the hypopharynx, the cricopharyngeus relaxes, allowing the hypopharyngeal bolus to enter the cervical esophagus. Equally important, the cricopharyngeus then closes to prevent esophagopharyngeal reflux (see Chapter 32).[19]

The pharyngeal plexus of nerves receives contributions primarily from the glossopharyngeal and vagus nerves. Lesser contributions come from the spinal accessory nerve and the sympathetic plexus. It is the vagus that primarily supplies motor innervation to the constrictor muscles.[19] Sensory information from the hypopharynx travels along the glossopharyngeal nerve and the internal laryngeal branch of the superior laryngeal nerve, a branch of the vagus nerve.[14] Pain from a hypopharyngeal tumor may be transmitted up from the pyriform sinus along the internal branch of the superior laryngeal nerve. The impulses may then continue along the vagus nerve to the auricular nerve, a branch of the vagus nerve. Since the auricular nerve (Arnold's nerve) supplies sensory innervation to the external auditory canal and pinna via this referred pathway, a hypopharyngeal tumor may present with otalgia.[14]

The pyriform sinuses are drained by a network of lymphatics, most of which are directed to levels II and III nodes and secondarily to level V nodes.[14, 16] The lymphatics of the posterior wall of the hypopharynx drain to the level II and III nodes, as well as to the retropharyngeal nodes.[16] The postcricoid lymphatics drain to level III and IV nodes as well as to level VI nodes (see Chapter 36).[20]

Branches of the superior and inferior thyroid arteries supply most of the lower pharynx.[1] The venous drainage more superiorly is into the pharyngeal plexus, while the drainage inferiorly is into the superior and inferior thyroid veins and into individual pharyngeal veins that drain directly into the internal jugular veins.[1]

IMAGING TECHNIQUES

Barium Studies

Barium studies allow both anatomic and dynamic assessment of the upper aerodigestive tract. These studies provide information regarding the integrity of the mucosa and can determine if the pharyngeal wall is pliable or fixed. A barium swallow is usually the first radiographic study performed in the evaluation of a patient with dysphagia and/or odynophagia (see Chapter 32) (Fig. 28-12). Barium studies can detect small mucosal abnormalities that are not apparent on either CT or MR imaging, and barium studies are helpful for detecting traumatic or iatrogenic perforations and postoperative fistulae. Because there is about a 10% incidence of second primary tumor in a patient with squamous cell carcinoma of the upper aerodigestive tract,

FIGURE 28-12 Pyriform sinus carcinoma—barium studies. **A**, The lateral wall of the right pyriform sinus (*black arrows*) is irregular with tumor on this frontal air-contrast study. The tumor spares the apex of the pyriform sinus (*curved arrow*). The lateral pharyngeal wall on the left is normal (*open arrows*). **B**, In another patient, a frontal view from a single-contrast barium study shows irregularities and filling defects (*solid arrows*) along the lateral wall of the left pyriform sinus. The right pyriform sinus wall is normal (*open arrows*).

virtually all of these patients should be followed with either periodic endoscopy or a barium swallow. These second cancers most often arise in the upper aerodigestive tract or the lung.[16]

Although barium is the contrast agent of choice for the routine evaluation of patients with dysphagia, a water-soluble iodinated medium is preferable when evaluating for a perforation, as these agents (diatrizoate meglumine and diatrizoate sodium) are readily absorbed from the soft tissues of the neck. However, these contrast agents are quite hypertonic (1900 mosm/kg water) and are contraindicated in a patient who may have significant aspiration.[21] Such aspirated hypertonic contrast media draw fluid into the lungs and can result in pulmonary edema. For such patients, the best contrast agents are low-osmolality, iodinated, water-soluble contrast media such as metrizamide and iohexol.[21] If a perforation to the tracheobronchial tree is suspected, either barium or a low-osmolality contrast agent is recommended.

Computed Tomography

The best CT evaluation of the pharynx is achieved on axial images with the patient supine. The head should be carefully aligned in the cephalocaudad axis, usually with the hard palate perpendicular to the table top and a scan plane parallel to the inferior orbital meatal plane. Poor positioning may result in an appearance that either simulates pathology or occasionally makes pathology difficult to see. Coronal imaging (either direct or reformatted) should also be performed in any patient suspected of having a nasopharyngeal, palatal, or skull base carcinoma, as early erosion of the

Copyright © 2003, Mosby, Inc. All rights reserved.

skull base and hard palate is best seen in the coronal plane. If the patient has dental amalgams or other oral cavity metal products that cause severe artifacts, additional scans should be performed through the region of degraded images with a gantry angulation along the plane of the mandible. All studies should be reconstructed in both soft-tissue and bone algorithms.

Spiral and multidetector CT are fast becoming the preferred techniques.[22–24] Due to their short imaging times, imaging of the pharynx can be performed in a single short breath hold or even with the patient breathing normally. Patient movement artifact is virtually eliminated. The optimal field of view (FOV) varies between 14 and 18 cm, with the final FOV dependent on the size of the patient. The preferred slice thickness is between 2 and 3 mm, and images are made contiguously through the neck.

If intravenous contrast is not contraindicated, such contrast is recommended for all CT studies of the neck. Intravenous contrast not only increases the conspicuity of pathology but is essential for evaluating the cervical lymph nodes (see Chapter 36). The use of a power injector is preferred, with an initial bolus injection of 50 cc followed by a continuous infusion to a total contrast volume of between 100 and 150 cc.

Magnetic Resonance Imaging

MR images of the nasopharynx and oropharynx can be performed with a head coil, while images to evaluate the hypopharynx and cervical lymph nodes must utilize a dedicated neck coil sufficient in size to cover the patient from the level of the floor of the mouth to the supraclavicular region. In order to obtain high-quality images, the patient must be instructed not to talk or move and, if possible, to minimize swallowing. If possible, the patient should not fall asleep, as snoring often degrades image quality.

For the routine MR examination, sagittal T1-weighted, spin-echo localizer images are obtained. Axial T1-weighted and fast spin-echo, T2-weighted images are then obtained through the field of interest. A coronal T1-weighted sequence also provides an additional orthogonal view of the skull base and superior nasopharynx.

The use of intravenous paramagnetic contrast is essential when evaluating patients with malignancies of the pharynx. The initial noncontrast T1-weighted images will have covered the primary region of interest. These important images allow areas of high T1-weighted signal intensity (i.e., fat, high protein content, methemoglobin) to be identified and thus not confused with areas of enhancement of the contrast-enhanced, T1-weighted images.

When studying lesions of the tongue base, sagittal images are helpful to assess the caudal and ventral extent of disease. Coronal scans of the oropharynx are generally not essential, but they can give a good assessment of the craniocaudal extent of disease. In addition, level V nodes are often better seen on coronal than on axial images.

Sections 4 or 5 mm thick, with a 1-mm interslice gap, are mandatory to prevent volume averaging. Proper acquisition parameters and filming are also essential for optimal imaging of the pharynx. An 18- to 20-cm FOV with a 512×256 matrix can be used in the nasopharynx and oropharynx in most patients without a phase wrap artifact. A smaller matrix (256×256) is recommended for the hypopharynx, as this will help increase the signal-to-noise ratio of this smaller region. Presaturation pulses are also helpful to reduce the often troublesome phase-encoding flow artifact.

Tissue Differentiation

In the pharynx, the three primary soft tissues that are imaged are muscle, lymphoid tissue, and fat, each with different CT and MR imaging characteristics.[25] The primary task of the radiologist is to differentiate these normal tissues from tumor and infection. On CT, muscle and lymphoid tissues are often difficult to distinguish from neoplastic tissues but are easily differentiated from fat (Fig. 28-13). On MR imaging, muscle has an intermediate T1-weighted and a low T2-weighted signal intensity. Lymphoid tissue has a signal intensity similar to that of muscle and of most tumors on T1-weighted images[25–28] (Fig. 28-13). However, lymphoid tissue has a relatively high T2-weighted signal intensity. Most cellular tumors have an intermediate T1-weighted and a slightly higher intermediate T2-weighted signal intensity, also allowing their distinction from muscle.

The T1-weighted images afford the best contrast between fat and muscle, whereas the T2-weighted images best demonstrate the contrast between muscle and tumor and lymphoid tissue.[25, 27, 28] Because of similar signal intensities, most tumors and lymphoid tissue cannot be reliably differentiated from each other on MR imaging.

The dominant fat plane on either side of the pharynx is the parapharyngeal space, which is best defined on T1-weighted images. In cases of pharyngeal tumor, infiltration of the parapharyngeal space fat usually indicates deep invasion of the neoplasm.

The tonsils and faucial pillars usually appear as bilaterally symmetric soft-tissue masses on either side of the oropharyngeal airway.[29–31] Any asymmetry in the size or configuration of these tonsils may indicate the presence of a tumor or infection in the larger side. A large cystic area within a palatine tonsil may indicate a lymphoma, a necrotic tumor, or an abscess. The presence of a well-defined enhancing rim around such an area suggests an abscess; however, because some tumors can also have this imaging appearance, the history in such cases is essential. The presence of infection is virtually always associated with pain and malaise. Tumor usually causes little, if any, pain. Dystrophic calcifications from prior infections are commonly seen within the tonsillar crypts (Fig. 28-6), and a benign minor salivary gland retention cyst may occur, usually either within the nasopharynx or palatine tonsils or in the hypopharyngeal mucosa (Figs. 28-14 and 28-15).

NEOPLASMS

General Considerations

The mucosa of the entire upper aerodigestive tract is potentially exposed to the same carcinogenic agents and risk factors. Thus, it is not surprising that multiple primary

VIEW IMAGE

tumors may develop, with an incidence of 10% to 35%. The second tumor is considered a synchronous lesion if it is discovered either at the same time or within 6 months of the diagnosis of the primary tumor. The second tumor is considered metachronous if it is diagnosed more than 6 months after the primary tumor. If, at the same time, two apparent tumors are identified in the upper aerodigestive tract, there must be normal mucosa separating them in order for them to qualify as synchronous cancers. Otherwise, they are considered one tumor. In general, most second tumors are metachronous. Second cancers are most often seen when the initial tumor is located in the oral cavity, oropharynx, or hypopharynx.[32] Nasopharyngeal carcinoma does not share the same associations.

Compared to patients with a single cancer, there is decreased survival in patients who have a second cancer. The best strategy to improve survival in these patients appears to be early detection of the second cancer. This is best accomplished by constant and regular vigilance, including serial imaging studies.

The most important epidemiologic factors in the development of upper aerodigestive tract cancers are tobacco use and alcohol use. Other risk factors include prior irradiation; work in the hardwood furniture, asbestos, or nickel industries; poor oral hygiene; Epstein-Barr virus infection; and betel nut chewing.[32] As a general statement, p53 overexpression has been reported to be a predictor of shorter survival due to the associated development of tumor recurrence and the appearance of a second primary tumor (see Chapter 45).

Several syndromes and diseases are associated with the development of cancers of the upper aerodigestive tract. These include Bloom's syndrome, Lynch-II syndrome, Fanconi's anemia, xeroderma pigmentosum, ataxia-telangiectasia, Li-Fraumani syndrome, and an immunocompromised state.[32]

Nasopharyngeal Carcinomas

Squamous cell carcinoma (SCCA) accounts for about 70% of the malignancies arising in the nasopharynx in adults.[5,6] Lymphomas account for approximately 20% of the cases. The remaining 10% are caused by a variety of lesions including adenocarcinoma, adenoid cystic carcinoma, rhabdomyosarcoma, melanoma, extramedullary plasmacytoma, fibrosarcoma, and carcinosarcoma.[6] SCCA of the nasopharynx is a relatively rare cancer that accounts for only 0.25% of all malignancies in North America. However, this tumor has a high incidence in Asia, where it is the most common cancer in males and the third most common cancer in females, accounting for 18% of all cancers in China.[33] In the United States, SCCA is more common in males than in females, with the majority of cases being diagnosed during the sixth decade of life.[6] The biologic behavior of nasopharyngeal carcinomas is the same, regardless of ethnic origin. The staging of nasopharyngeal cancer (NPC) is presented in Table 28-1.[15]

Several factors have been linked to an increased likelihood of developing NPC. IGA antibodies against Epstein-Barr virus have been associated with the undifferentiated form of this tumor, while HLA-A2 and HLA-B-Sin histocompatibility loci have been identified as possible markers for genetic susceptibility to SCCA among the Chinese population.[34] The incidence of this tumor decreases among Chinese born in North America, although the rate is still seven times higher than that in native Americans.[35] Other potential risk factors include nitrosamines (present in dry, salted fish), polycyclic hydrocarbons, poor living conditions, and chronic sinonasal infections.[6] Recent studies have also identified associations between genetic alterations involving specific loci on chromosomes 11q, 9q, and 3p.[36–39]

The World Health Organization (WHO) histologic classification for NPC has recently been updated and

Table 28-1

recognizes two major subtypes of NPC: squamous cell carcinoma (1) and nonkeratinizing carcinoma (2).[40] The squamous cell type is similar to other SCCA found in the remainder of the upper aerodigestive tract. The nonkeratinizing subtype is further subdivided into differentiated (2a) and undifferentiated (2b) forms.[40] Because NPC is often heavily infiltrated by lymphocytes, the term *lymphepithelioma* has been used to describe the nonkeratinizing subtypes (2a and 2b). It should be noted that subtypes 2a and 2b correspond with the original WHO types 2 and 3, respectively.[40]

The clinical presentation depends on the size and location of the lesion, with most small lesions being asymptomatic. The most common presenting complaint is level II to V lymphadenopathy. NPC carcinoma is one of the few head and neck primary tumors with no relationship between primary tumor size and the presence of nodal disease. Large tumors may have no nodal metastasis, while small tumors may present with diffuse, bilateral cervical metastases. Serous otitis media, caused by eustachian tube obstruction, may also be a presenting complaint. Other symptoms include headaches, nasal obstruction, epistaxis, sore throat, trismus, and proptosis. Advanced lesions may spread to the adjacent cranial nerves and present with neurologic symptoms. Thus, tumor extension into the cavernous sinus may result in palsies of cranial nerves III to VI, while tumor in the poststyloid parapharyngeal space may involve cranial nerves IX to XII and the sympathetic chain.[5, 6]

The standard treatment of NPC is external beam supervoltage irradiation, with brachytherapy being of some benefit in selected individuals.[5, 6, 41] For more advanced tumors, combined chemotherapy and radiation therapy is now gaining acceptance as the alternative treatment of choice.[42, 43] Surgery plays a very limited role in the treatment of NPC because adequate surgical margins are difficult to obtain. However, if neck disease persists or recurs after radiotherapy, a neck dissection is usually performed to control the disease.[5, 6] The reported 5-year survival rates for patients treated with radiation therapy at M.D. Anderson Hospital vary with the histologic type and are as follows: SCCA (42%), lymphoepithelioma (65%), and unclassified carcinomas (14%).[44] However, the overall prognosis is dependent on other factors including the size of the primary lesion, extent of disease, duration and extent of symptoms, presence of skull base erosion, and nodal involvement at multiple levels.

Imaging Features

CT and MR imaging play essential and complementary roles in the staging and treatment of patients with NPC (Table 28-2) (Fig 28-16). As imaging studies usually are unable to differentiate between SCCA and other malignancies, the primary role of imaging is accurate tumor mapping. The most reliable imaging finding of a malignancy is that of an aggressive, often enhancing mass that infiltrates the deep fascial planes and spaces about the nasopharynx[7] (Figs. 28-17 and 28-18). A noninfiltrating, homogeneously enhancing mass situated on the mucosal surface may either be a low-grade tumor or prominent adenoidal tissue, and clinical correlation should be requested (Fig. 28-13). MR imaging provides excellent visualization of the soft-tissue planes of the nasopharynx and is superior to CT for detecting perineural spread of tumor (Fig. 28-19).[45, 46] Both CT and MR may be used for identifying skull base invasion. CT is superior to MR for identifying early cortical invasion, while MR is superior to CT for detecting marrow involvement [47] (Figs. 28-20 to 28-23).

NPC tend to grow along the path of least resistance. Potential pathways of tumor extension include growth along muscle bundles, neurovascular bundles, fascial planes, and within the mucosa and submucosa. However, the natural spread of tumor may be altered by certain normal structures that are relatively resistant to tumor invasion. In the nasopharynx, such structures are the cartilaginous portion of the eustachian tube and the pharyngobasilar fascia [7, 11, 48, 49] (Fig. 28-16).

As mentioned, small lesions are often limited by the surrounding pharyngobasilar fascia[45] (Fig. 28-24). However, once this barrier is breached, the tumor may directly invade the skull base; the most common sites of intrusion are the region of the petroclival fissure and the foramen lacerum. Aggressive lesions may extend into the foramen lacerum, encase the internal carotid artery, and gain access to the cavernous sinus (Fig. 28-25). Skull base erosion is also likely to occur at sites of musculature attachments, and the levator and tensor veli palatini muscles provide common pathways for cranial tumor spread.[7, 11, 48, 49]

As previously mentioned, the upper anterior portion of the lateral wall of the nasopharynx (pharyngobasilar fascia) is incomplete due to the sinus of Morgagni, through which passes the cartilaginous portion of the eustachian tube and the levator veli palatini muscle.[5] However, this natural defect also allows passage of tumor into the parapharyngeal region and retrograde perineural spread along V_3 into the cavernous sinus (Fig. 28-26). Such nerve or perineural invasion should be suspected when there is enlargement and abnormal enhancement of the nerve with obliteration of the surrounding fat planes. Tumors may also directly invade the skull base at the foramen ovale, and CT and MR imaging can help determine whether tumor has invaded the sphenoid sinus.[46, 47]

Tumor extension may also involve the pterygopalatine fossa and/or posterior aspect of the nasal cavity; however, invasion of the posterior ethmoids, orbit, and maxillary antrum is unusual (Fig. 28-27). Caudal tumor extension along the lateral pharyngeal walls and the anterior and posterior tonsillar pillars is seen in nearly 33% of patients.[5] This form of spread is often submucosal and may be clinically occult.

Imaging of all of the cervical lymph nodes is essential because 85% to 90% of patients have nodal spread at the time of initial diagnosis, and nearly 50% of patients have bilateral disease.[5, 44, 50, 51] The retropharyngeal nodes are usually the first nodes to be affected; however, level II nodes may be involved without imaging evidence of retropharyngeal nodal disease.[51–53] Level I nodes and occipital nodes typically become affected only after alteration of the primary lymphatic drainage, as found following radiation therapy.[5]

Oropharyngeal Carcinomas

The majority of tumors involving the oropharynx are SCCA, followed by other, less common neoplasms such as lymphoma, minor salivary gland tumors, and other rare mesenchymal lesions. The incidence of SCCA of the oropharynx increases in patients with a history of tobacco or alcohol abuse. The staging system for these tumors is presented in Table 28-3.[15] Because the spread patterns and lymphatic drainage vary with the site of origin, tumors arising in the anterior tonsillar pillar, posterior tonsillar pillar, tonsillar fossa, soft palate, and tongue base will be discussed separately.

Anterior Tonsillar Pillar

The anterior tonsillar pillar (ATP) is a mucosal fold over the palatoglossus muscle, and tumors arising on the ATP tend to spread along this muscle and its fascial attachments. Thus, tumors may extend superiorly to involve both the soft and hard palates. From the palate, the tumor may continue to extend superiorly along the tensor and levator veli palatini muscles and the pterygoid muscles to the skull base[54, 55] (Fig. 28-28). Such an advanced tumor spread pattern may be confused with that of a large NPC that has spread inferiorly. However, extensive ATP lesions tend to invade and extend into the ipsilateral nasopharynx and masticator space, whereas large NPCs tend to involve the nasopharynx bilaterally.

Anteriorly and medially, ATP lesions may also spread along the superior constrictor muscle to the pterygomandibular raphe and from there to the buccinator muscle. This spread pattern mimics that of a tumor arising in the retromolar trigone region. Tongue base invasion may also be present in large lesions and is most likely a result of inferior tumor growth along the palatoglossus muscle[54–56] (Table 28-4).[22]

Table 28-3
1997 AMERICAN JOINT COMMITTEE ON CANCER STAGING FOR EPITHELIAL TUMORS OF THE OROPHARYNX

TIS	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4	Tumor invades adjacent structures (e.g., pterygoid muscle(s), mandible, hard palate, deep muscle of tongue, larynx)

The lymphatic drainage of ATP tumors is primarily to level I, II, and III nodes. However, because the lymphatic drainage is determined by the site of the tumor, a lesion spreading to the soft palate and above will acquire the drainage pattern of this area. The overall likelihood of positive nodes with ATP carcinomas at presentation is 45%, although the incidence is dependent on the stage of the disease as follows: T_1, 11%; T_2, 38%; T_3, 54%; and T_4, 68%.[54, 58] The likelihood of nodal involvement in a clinically negative neck (N0) is 10%; contralateral nodal involvement has been reported to occur in 5% of cases.[54]

Posterior Tonsillar Pillar

The posterior tonsillar pillar (PTP) is a mucosal fold over the palatopharyngeus muscle. Isolated PTP lesions are rare, and when present are usually small. PTP lesions may spread along the course of the palatopharyngeus muscle, and superior extension may involve the soft palate, while inferior growth may involve the posterior aspect of the thyroid cartilage, the middle pharyngeal constrictor, and the pharyngoepiglottic fold[54] (Table 28-4).[22]

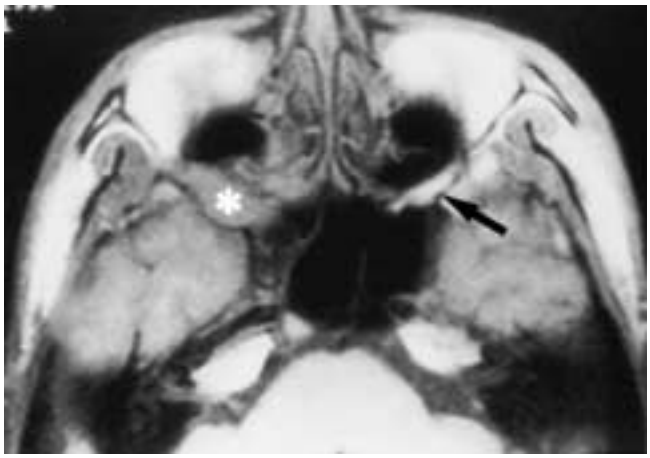

FIGURE 28-27 Axial noncontrast T1-weighted MR image shows enlargement of the right pterygopalatine fossa (*). FIGURE 28-28 Superior extension into the nasopharynx from tonsil carcinoma. **A**, Axial contrast-enhanced CT scan through the oropharynx demonstrates a right tonsil carcinoma (*arrows*). **B**, Axial scan obtained through the nasopharynx in the same patient illustrated in **A** shows asymmetric enlargement of the right torus tubarius (*arrow*). These findings are indicative of superior extension of the tumor. Based on these findings, the patient was treated nonsurgically.

Although the primary lymphatic drainage is to the level II nodes, if these tumors spread posteriorly, they can involve the posterior pharyngeal wall and place the retropharyngeal and level V nodes at risk.[54]

Tonsillar Fossa

Malignancies of the tonsillar fossa are believed to arise from the mucosa lining the niche between the ATP and PTP or from remnants of the palatine tonsil.[54] Tumors in this location often are clinically occult and present with cervical nodal metastases without an obvious primary tumor. Given their location, these lesions may spread anteriorly or posteriorly to involve the adjacent tonsillar pillars, thereby acquiring the potential spread patterns associated with these sites (Fig. 28-29). These lesions may also extend deeply and invade the superior constrictor muscle, thus gaining access to the parapharyngeal space and skull base[22,54–56] (Table 28-4)[22] (Fig. 28-30).

The primary lymphatic drainage for the tonsillar fossa is to level I to IV nodes and occasionally to level V and the parotid nodes. Tumors arising within the tonsillar fossa have an overall 76% chance of having clinically positive nodal metastases. Specifically, the likelihood of having clinically positive nodes for tonsillar fossa tumors is as follows: T_1, 71%; T_2, 68%; T_3, 70%; and T_4, 89%.[57] The incidence of involved contralateral nodes is 11% and increases if the lesion invades the tongue base or spreads across the midline of the soft palate.[24, 25]

Table 28-4
IMAGING CHECKLIST FOR OROPHARYNGEAL CARCINOMA

Tonsil, Soft Palate, or Posterior Pharyngeal Wall Carcinoma
• Detailed evaluation of submucosal extension into the soft tissues of the neck (pre- and poststyloid parapharyngeal space, nasopharynx)
• Tongue base invasion
• Encasement of carotid artery
• Bone erosion
• Prevertebral muscle invasion
Tongue Base Carcinoma
• Extension to floor of mouth and surrounding structures
• Relationship to ipsilateral lingual neurovascular bundle
• Extension across midline and relationship to contralateral neurovascular bundle

Soft Palate

The majority of soft palate malignancies are SCCA; however, minor salivary gland cancers also have their highest frequency in the posterior hard palate and soft palate. Carcinomas of the palate usually affect the oral aspect, tend to be well differentiated, and have the best prognosis of all of the oropharyngeal carcinomas. The nasopharyngeal side of the soft palate is rarely involved, even when the tumors are extensive. Although tumor extension of palatal cancer can occur in any direction, the tonsillar pillars and hard palate are usually affected first. Deep lateral invasion occurs along the levator or tensor veli palatini muscles and into the parapharyngeal space, nasopharynx, and base of the skull[22] (Fig. 28-31).

At the time of diagnosis, lymphatic spread is present in 60% of patients. The incidence of cervical node metastases depends on the size of the primary lesion, with T_1 carcinomas having an 8% incidence and T_4 tumors having a 70% incidence. Palatal carcinomas drain to level II nodes first, and then to the level III and retropharyngeal nodes. Tumor extension up the greater and lesser palatine nerves can also occur, allowing spread into the pterygopalatine fossa and then via the foramen rotundum to the cavernous sinus.

The treatment of palatal lesions depends on the stage of the disease. Advanced lesions such as T_2 and T_3 carcinomas are usually treated with both surgery and radiation to the primary tumor and cervical lymph nodes. However, because surgery requires wide excision, there may be a significant

FIGURE 28-29 **A**, Noncontrast T1-weighted image demonstrates a left tonsillar carcinoma (*T*). Based on the clinical examination, the tumor was believed to be resectable. **B**, Axial noncontrast MR image through the nasopharynx performed in the same patient illustrated in **A** shows a mass deep to the left torus tubarius that was suspicious for superior extension into the nasopharynx (*arrows*). **C**, Axial CT scan through the skull base (same patient illustrated in **B**) reconstructed in bone algorithm shows no evidence of skull base invasion. **D**, However, axial noncontrast T1-weighted image through the skull base (same patient illustrated in **C**) shows replacement of the normal signal in the petrous bone by intermediate signal (*arrows*). These findings were suspicious for skull base invasion. Based on these findings, the patient was believed to be inoperable and died 3 weeks after these studies.

postoperative defect causing difficulty with phonation and swallowing (nasal regurgitation).[58]

The CT findings of soft palate carcinomas vary with the size of the lesion. Small oral surface lesions are best seen on direct clinical examination. Larger lesions may cause unilateral fullness in the region of the soft palate and tonsil, and there may be invasion of the parapharyngeal space.[59] Direct coronal imaging must be used to evaluate the soft and hard palates because these structures lie in the axial plane and thus are often poorly seen (Fig. 28-32). MR imaging is ideally suited to evaluate the palate in both the sagittal and coronal planes[60] (Fig. 28-33). In general, T1-weighted images suffice, as the palate has a high concentration of mucous glands and normally has a high signal intensity. The tumor is usually well seen as an area of lower signal intensity. T2-weighted images and contrast-enhanced images often provide little additional information (Table 28-4).[22]

Base of the Tongue

The tongue base is defined as the area posterior to the circumvallate papilla, and it extends inferiorly to the vallecula[22] (Fig. 28-34). The tongue base contains varying amounts of lingual tonsil; for this reason, it is often difficult to diagnose small tumors with either CT or MR imaging. Superficial lesions detected by direct visualization may not be seen on imaging studies. In addition, the fat planes that are normally seen in areas such as the floor of the mouth and

masticator space, and that allow detection of subtle lesions, are not as evident in the base of the tongue. Rather, this area consists mostly of the dense tongue musculature.

Tongue base carcinomas are often clinically silent, and the tongue base is a common location of ''occult'' malignancies originating in the upper aerodigestive tract. Because of this, these lesions often have progressed to an advanced stage at the time of initial presentation[54, 55] (Fig. 28-35).

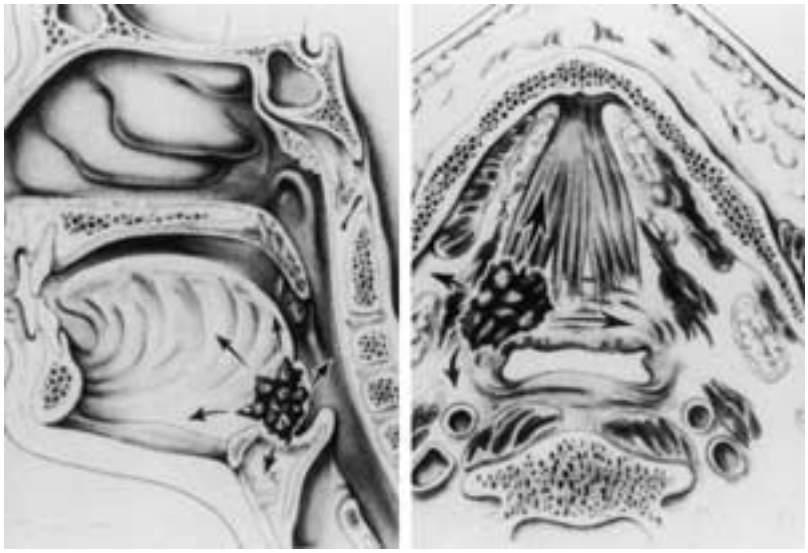
On MR imaging, noncontrast T1-weighted images are often most helpful to visualize the full extent of these lesions and specifically to help determine whether the tumor has crossed the midline. This is especially important if the patient is a candidate for partial glossectomy.

Malignancies of the tongue base often are limited to one side of the tongue, crossing the midline only when the tumor becomes large. These tumors may also spread to the tonsillar pillar, pharyngeal wall, anteriorly into the sublingual space, and submucosally under the valleculae into the supraglottic larynx[54] (Fig. 28-36). If surgery is the treatment, this latter spread is critical to identify, as it determines if a partial or total laryngectomy is required. The hyoepiglottic ligament can usually be seen on imaging (see Chapter 30), and tumor extension below this structure indicates spread into the preepiglottic space of the larynx. Lesions may also grow inferiorly and laterally to spread into the deep soft tissues of the neck, eventually involving the styloid musculature and the internal carotid artery[54, 55] (Table 28-4).[22]

The tongue base has a rich lymphatic network with a significant amount of cross-drainage, explaining why nearly 30% of patients have bilateral cervical metastases at initial presentation.[24, 57] The primary lymphatic drainage is to level II to IV nodes, with occasional involvement of level V nodes. Tumor spread to the floor of the mouth may also involve level I nodes. Overall, 75% of patients have positive nodes on clinical examination. When nodes are analyzed by tumor stage, the incidence of clinically positive nodes is as follows: T_1, 70%; T_2, 70%; T_3, 75%; and T_4, 84%.[57] Presumably because of the rich lingual lymphatic network and the often advanced stage at which these tumors are discovered, there is a high incidence (nearly 60%) of nodal metastases in clinically negative necks.[53, 54, 61] In these cases, the cervical nodes must be carefully scrutinized on CT or MR imaging, as identification of clinically occult nodal disease will alter treatment.

HYPOPHARYNGEAL CANCERS

Over 95% of all hypopharyngeal tumors are SCCA[14] (Table 28-5). Risk factors include alcohol abuse, smoking, and previous radiation therapy.[14] Hypopharyngeal tumors can remain asymptomatic for a long time.[14] Occasionally, patients with hypopharyngeal carcinomas may present with referred pain. This referred pain travels up from the pyriform sinus along the internal laryngeal nerve of the vagus nerve and then along the auricular nerve (Arnold's nerve) of the vagus to the external auditory canal and pinna.[19] Tumors originating from the hypopharynx, in addition to those



VIEW IMAGE

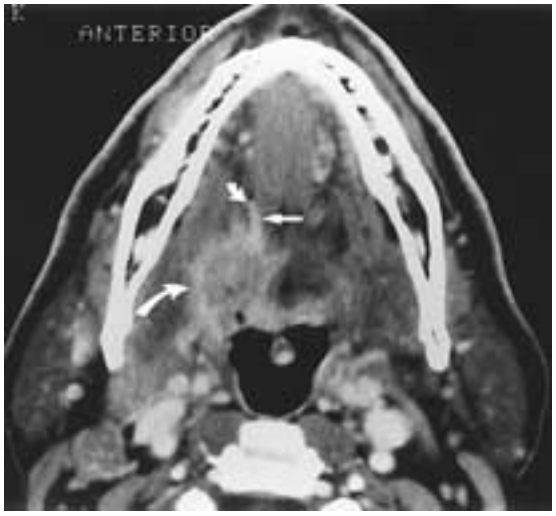
arising from the tongue base, tonsil, and nasopharynx, must be included in the differential diagnosis of patients who present with otalgia.[14] Up to 75% of patients with hypopharyngeal tumors have metastases to cervical lymph nodes at the time of initial diagnosis.[14] Up to 15% of patients with SCCA of the hypopharynx have a synchronous (25%) or metachronous (40%) second primary tumor.[14]

Superficial mucosal lesions in the pyriform sinus are best evaluated by direct clinical observation and by barium studies. On CT and MR studies, a collapsed (nondistended) pyriform sinus can mimic a tumor. Conversely, it is not always possible to exclude a tumor when the pyriform sinus is not normally distended.[14] Submucosal spread may not be apparent on direct clinical inspection but usually is well seen on CT and MR imaging. As the apex of the pyriform sinus is located at the level of the true vocal cords, and as the anterior wall of the pyriform sinus is the posterior surface of the paraglottic space, tumor spread into the larynx may occur; this is well seen on imaging[8, 22] (Figs. 28-37 to 28-40) (Table 28-6).

Pyriform sinus carcinomas may spread submucosally into the posterior wall of the hypopharynx, along the anterior wall in the postcricoid region, or along the medial wall (the aryepiglottic fold).[8] Large tumors may extend into the paraglottic and preepiglottic fat and the base of the tongue (Fig. 28-39).[8, 14] Tumors arising from the lateral wall or apex of the pyriform sinus often have already invaded the thyroid cartilage at the time of diagnosis.[8, 14] Lesions involving the aryepiglottic fold may spread into the false vocal cord and arytenoid cartilage.[8, 14] Involvement of the hypopharynx may lead to tumor spread to the contralateral pyriform sinus.

Tumors confined to the postcricoid region are rare [14] (Fig. 28-41). Tumors can invade the posterior larynx (arytenoid and posterior cricoid cartilage), causing vocal cord paralysis



VIEW IMAGE

FIGURE 28-36 Axial contrast-enhanced CT scan shows the characteristic appearance of a tongue base carcinoma (*large curved arrow*). There is extension into the floor of the mouth (*small straight arrow*), with infiltration and obliteration of the fat surrounding the lingual vessels (*small curved arrow*), suggesting perineural or perivascular invasion of tumor. This was confirmed at histologic examination of the resected specimen.

and hoarseness (Figs. 28-42 and 28-43). Large tumors concentrically infiltrate and narrow the lumen of the hypopharynx and may extend through the cricopharyngeus to the inlet of the cervical esophagus (esophageal verge).[14] Inferior tumor extension to involve the esophageal verge and cervical esophagus may alter the surgical treatment and, if undetected preoperatively, may result in a positive surgical margin.

A well-known risk factor for developing cancer of the postcricoid hypopharynx is the Plummer-Vinson syndrome (also known as the Paterson-Brown syndrome).[8] This syndrome is more common in women than men. Its four components are dysphagia, iron-deficiency anemia, weight loss, and webs in the hypopharynx and cervical esophagus.[14] The associated carcinomas are usually in the postcricoid region, perhaps related to stasis above the webs.

Carcinomas of the posterior wall of the hypopharynx spread cranially and caudally along the posterior wall. These tumors may spread submucosally and be quite bulky at initial presentation.[8,14] Tumor may extend up into the posterior wall of the oropharynx and even infiltrate the posterior aspect of the tonsillar pillars.[8, 14] Invasive posterior wall tumors may extend into the prevertebral muscles and may even invade the vertebrae. Obliteration of the prevertebral fat planes by tumor on CT and MR imaging should raise the suspicion of tumor fixation to the longus coli muscles[8] (Fig. 28-43). Such muscle invasion is best seen on T2-weighted MR imaging, where the normal low signal intensity of the muscle is replaced by the intermediate signal intensity of tumor. However, in nearly half of the cases with such MR findings at surgery, the muscles are not invaded. The altered signal intensity in these cases reflects inflammation of the muscles. Nonetheless, such an MR finding should be considered to reflect muscle invasion until proven otherwise.

LYMPHOMAS

Lymphoma is the most common lymphoproliferative disorder occurring in the extracranial head and neck.[62] Hodgkin's disease (HD) is a malignancy of the hematopoietic system that predominantly affects adolescents and young adults, with males being affected more frequently than females (2:1). The diagnosis of HD is strongly suggested by the presence of Reed-Sternberg cells on nodal biopsy. Extranodal disease in the head and neck is rare. Overall, the most common extranodal site is the spleen, often associated with liver involvement. Bone marrow involvement is believed to result from hematogenous spread, whereas pulmonary involvement is thought to be secondary to direct extension from hilar and mediastinal lymph nodes.[62, 63]

Non-Hodgkin's lymphoma (NHL) is most commonly seen in older patients than those affected by HD. Males are more commonly affected than females, and predisposing conditions include various congenital and acquired immunodeficiency states. The most commonly used classifications of NHL are those of Rappaport and of Lukes and Collins. The Rappaport system is based on the resemblance of the various malignant cells to their benign counterparts, whereas the Lukes and Collins system is based on immunologic markers that separate the tumor cells into B-cell, T-cell, and histiocytic types.

Unfortunately, the majority of patients with NHL have advanced disease at the time of presentation. Whereas 98% of HD patients present with nodal disease, 60% of NHL patients present with disease in extranodal sites, and 60% of all extranodal presentations occur in the head and neck.[64] The extranodal areas predisposed to develop lymphoma are those areas normally rich in lymphoid tissue such as Waldeyer's ring. Other primary sites in the extracranial head and neck include the parotid gland (15% of these patients

have a prior history of Sjögren's syndrome), palate, gingiva, lacrimal gland, eyelid, conjunctiva, and paranasal sinuses.[62]

Typically, patients with HD present with a painless mass or complain of systemic symptoms such as night sweats, fever, and weight loss. The clinical symptoms of patients with extranodal NHL often mimic those of patients with SCCA arising at the same site. Thus, patients with NHL arising in the nasopharynx may present with nasal obstruction or unilateral serous otitis media, whereas patients with tonsillar or tongue base NHL complain of unilateral sore throat, dysphagia, or other obstructive symptoms. Nodal involvement is present in 80% of patients with NHL who present with extranodal primary lesions.[62]

The treatment of HD and NHL must be individualized, and depends on the stage of disease and the histologic type. Potential treatment modalities include radiation therapy, chemotherapy, and occasionally surgery for a localized extranodal NHL site.[62]

Imaging Findings

The imaging findings of extranodal head and neck lymphomas are essentially indistinguishable from those of the more common SCCA (Figs. 28-44 and 28-45). The diagnosis may be suggested if the primary lesion is associated with large, homogeneously enhancing lymph nodes that do not have central necrosis. However, this combination of findings may also be seen in poorly differentiated SCCA. As mentioned, the high concentration of lymphoid tissue in the tongue base and palatine tonsil makes these areas likely sites for the development of lymphoma (Figs. 28-44 to 28-46). Lymphoma should be suggested in the differential diagnosis, especially in tumors that occur in the region of Waldeyer's ring. Large lesions may infiltrate the deep spaces and mimic advanced SCCA radiographically. Primary nasopharyngeal lymphoma may invade the skull base and spread along nerves in a manner similar to that of SCCA. In other cases, the diagnosis of a nasopharyngeal lymphoma may be suggested by the imaging appearance of a bulky mucosa-based mass that has not violated the deep fascial planes about the pharynx. Ultimately, the diagnosis of lymphoma and the other lymphoproliferative disorders is based on histologic examination of tissue.

MINOR SALIVARY GLAND TUMORS

The minor salivary glands are distributed within the mucosa of the upper aerodigestive tract. Their greatest concentration is in the oral cavity and oropharynx, where it has been estimated that there are between 500 and 1000 minor salivary glands. They are also found throughout the pharynx, larynx, trachea, and major bronchi. For the most part, the same tumors arise in the minor salivary glands that arise in the major salivary glands.

Minor salivary gland tumors (MSGT) account for 2% to 3% of all malignancies of the extracranial head and neck.[65] These tumors most commonly occur in adults, and there is no reported sex predilection. The most common MSGT include adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, malignant mixed tumor, acinic cell carcinoma, and pleomorphic adenoma (Figs. 28-47 and 28-48). Depending on the series, benign tumors comprise approximately one half of MSGT versus about 70% to 80% of parotid tumors.

The soft palate is the most common site of MSGT, where their incidence is almost equal to that of SCCA. These tumors are usually off midline, in the posterolateral portion of the soft palate, and they are not typically found anterior to a line drawn between the first upper molar teeth.[65] These lesions may spread directly anteriorly to invade the hard

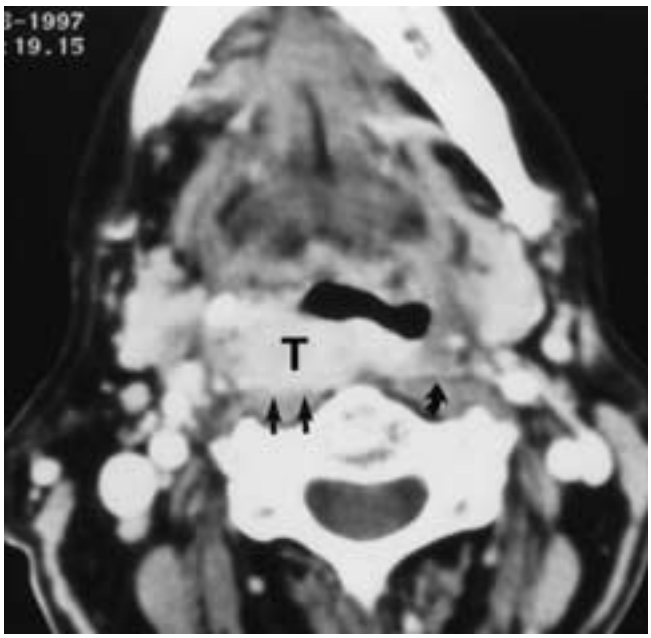

FIGURE 28-43 Axial contrast-enhanced CT scan demonstrates a posterior pharyngeal wall carcinoma situated at the level of the oropharynx (*T*). palate (Fig. 28-49). Other extracranial sites include the lips, gingiva, buccal mucosa, tongue base, floor of the mouth, paranasal sinuses, nasal cavity, nasopharynx, hypopharynx, larynx, and trachea (Figs. 28-27 and 28-28).

Imaging Features

The radiographic findings of these tumors are nonspecific, and the diagnosis is based on endoscopy and biopsy. Although CT and MR imaging play complementary roles in evaluating patients with malignant MSGT, the full extent of the tumor and any perineural spread is best evaluated with MR imaging. Bone invasion is best seen on CT, and both axial and coronal contrast-enhanced images (no greater than 3-mm contiguous sections) should be taken through the palate. Intraoral films or DentaScan-type CT images are also recommended for evaluating early bone erosion, especially if the lesion is adjacent to the lingual surface of the maxillary alveolar ridge.

Adenoid cystic carcinoma has a strong predilection to spread along perineural pathways, with such disease being diagnosed histologically in approximately 50% of cases. Continued tumor growth may eventually extend into the skull base and cavernous sinus and, if unrecognized, may be a cause of treatment failure (see Chapter 13). To further complicate matters, perineural spread may occur with skip areas of intervening normal nerve. Some investigators have suggested that this propensity for perineural spread may be due to the production of a substance that promotes adhesion to neural elements (neural cell adhesion molecule [NCAM]).[66] The role of mutations in the genome that normally produces the suppressor protein p53 and their relationship to the recurrence of adenoid cystic carcinoma are also currently being investigated.[67] Perineural spread can be identified with MR imaging; however, the extent of perineural spread is often underestimated.[68] This is especially true of lesions that arise in the soft palate because of their proximity to the pterygopalatine fossa. Obliteration of the fat in this fossa, or erosion or asymmetric enlargement of the greater and lesser palatine foramina, are findings highly suggestive of perineural tumor spread (Fig. 28-29) (see Chapter 13).

In the oropharynx, the risk of nodal involvement is directly related to the size, grade, and location of the primary lesion. The likelihood of cervical metastasis increases in sites that are rich in lymphatic drainage, and the chance of nodal metastasis for nasopharyngeal and oropharyngeal tumors is nearly eight times greater (59% vs. 7%) than that for tumors arising in the paranasal sinuses.[65] Thus, imaging should always include the entire neck if such potential nodal metastases are to be identified.

RHABDOMYOSARCOMAS

Rhabdomyosarcomas are uncommon mesenchymal malignant tumors found throughout the body.[69, 70] About 30% of these tumors involve the head and neck, with the orbit and nasopharynx being the most frequently involved sites, followed by the paranasal sinuses and the middle ear. These tumors occur primarily in young children, but they may occur in adolescents and rarely in adults.[71] The initial symptoms may be abrupt or insidious, depending on the location of the tumor. Nasopharyngeal rhabdomyosarcomas usually present with rhinorrhea, sore throat, and serous otitis media. Invasion of the skull base is common and often produces a cavernous sinus syndrome. Local recurrence and distant metastases are also common. Combined therapeutic regimens with chemotherapy, radiation therapy, and surgery have improved response rates to more than 60% to 70%.[72] The 5-year survival rate after recurrence is less than 5%.

Imaging Features

On CT, nasopharyngeal rhabdomyosarcoma appears as an aggressive infiltrating soft-tissue mass that destroys the skull base and posterior maxillary sinus.[73] The MR imaging features of rhabdomyosarcoma are also similar to those of SCCA (Fig. 28-50); however, rhabdomyosarcomas are primarily submucosal tumors. They show a variable amount of enhancement following contrast administration. In children, malignant tumors that may mimic rhabdomyosarcomas of the nasopharynx include neuroblastoma and rhabdoid tumor (Fig. 28-51).

GRANULAR CELL TUMORS

Granular cell tumors (GCT) are unusual benign neoplasms that can be found throughout the body.[74] They occur most often in the fourth decade of life, and they are more common in females than in males (2:1) and in African Americans than in Caucasians (5:1). Multiple GCT occur in approximately 4% to 10% of patients.

About 50% of GCT occur within the tongue, and approximately 30% arise in the skin. The remaining GCT

VIEW IMAGE

are seen in the breast, muscle, bronchi, temporal bone, and other areas of the upper respiratory and digestive tracts.[74] Most of the GCT found in the upper aerodigestive tract are intraluminal and solitary; however, synchronous lesions do occur and, when present, tend to behave more aggressively.[75] When these lesions occur in the larynx, the most common location is the posterior aspect of the true vocal cords, although GCT have been reported in the subglottic and supraglottic larynx.[75]

GCT of the upper aerodigestive tract occur in two forms. One type occurs in the gingiva of newborns and has been termed *congenital epulis*. The second type occurs later in life, arises predominantly within the submucosa of the upper respiratory and digestive tracts, and is referred to as *granular cell tumor*. Although these lesions are similar histologically, they are considered to be separate diagnostic entities because of their respective locations and the ages of the patients.

The histogenesis of GCT is controversial, and this has led to a variety of terms including Abrikosov's tumor, congenital epulis, nonchromaffin paraganglioma, granular cell myoblastoma, granular cell neurofibroma, myoblastic myoma, uniform myoblastoma, and embryonal rhabdomyoblastoma.[75] GCT is now believed to be of primitive neuroectodermal origin, and the term *granular cell tumor* is thought to be most appropriate.

(**A** and **B** courtesy of Dr. H. Ric Harnsberger, University of Utah.)

Histologically, this tumor has a characteristic appearance. Its cells are polymorphic, ranging from a definite polyhedral shape to a bizarre spindle form, and mitoses are uncommon.[76] The tumor cells are embedded in variable amounts of connective or reticular tissue, and they may extend into the adjacent fibrous stroma. GCT are often circumscribed but not encapsulated.

Imaging Features

The imaging features of a laryngeal lesion are thought to be typical of this lesion, which occurs anywhere in the upper aerodigestive tract. On MR imaging, GCT have a slightly low T1-weighted signal intensity, and they homogeneously enhance. On T2-weighted images they may have either increased or decreased signal intensity. On CT these lesions are solid and relatively homogeneously enhancing (Fig. 28-52). Radiographically, GCT may mimic a primary SCCA.

OTHER TUMORS

Rhabdomyomas

Rhabdomyomas are rare benign skeletal tumors that have a predilection for the head and neck. Whereas cardiac rhabdomyomas affect patients with tuberous sclerosis, extracardiac rhabdomyomas have no relationship to this syndrome. Affected regions include the oropharynx, nasopharynx, larynx, and submandibular triangle. On CT and MR imaging the tumors are well circumscribed, with a density or signal intensity similar to that of muscle. A subgroup of rhabdomyomas occur in newborns and children less than 3 years of age. These so-called fetal rhabdomyomas may actually be hamartomatous malformations rather than true neoplasms (Fig. 28-53).[77]

Fibromatoses

Fibrous lesions of the head and neck vary in their biologic activity and histologic appearance. Even though in some cases their histologic appearance is benign, they may be so locally aggressive that they are considered to be low-grade fibrosarcomas. The term *desmoid* has also been applied to a subgroup of these lesions, which present as well-differentiated but locally infiltrating fibrous masses near the musculoaponeurotic junctions. Of desmoids, 12% involve

the region of the head and neck, most commonly the soft tissues of the supraclavicular region and face.[78] Involvement of the oral cavity or nasopharynx is rare in adults, and the CT findings of the fibromatoses are nonspecific. Desmoids involving the head and neck usually encase and infiltrate the musculature of the supraclavicular region. They may infiltrate fat planes, and on CT they cannot be differentiated from malignant lesions (Fig. 28-54).

Schwannomas and Neurofibromas

Of all schwannomas, 25% are located in the head and neck region, and most involve the cranial nerves. The tongue, palate, and floor of the mouth are the most frequent sites in the oral cavity. Most schwannomas are diagnosed in the second and third decades of life as asymptomatic enlarging masses. On CT they are solitary, ovoid, well-encapsulated masses.[79] Small lesions are usually homogeneous, whereas focal cystic areas are often present in larger masses. These tumors enhance, despite the fact that they are relatively hypovascular.[79] On MR imaging, schwannomas have low T1-weighted and high T2-weighted signal intensity, and they enhance with contrast (Figs. 28-55 and 28-56). Neurofibromas of the oral cavity are rare lesions that are usually associated with von Recklinghausen's syndrome.[80] The tongue is the most frequent oral region affected, and unilateral macroglossia is a characteristic finding (Figs. 28-55 and 28-56).

Hemangiomas

In children, hemangiomas are the most common tumor in the cervical region. They may involve the oropharynx or face, usually as a sessile reddish submucosal mass near the base of the tongue. The cavernous type is most common. CT demonstrates a mass of muscle density that may or may not enhance. If present, phleboliths are diagnostic. MR imaging demonstrates an infiltrative mass of low T1-weighted and high T2-weighted signal intensity (Fig. 28-57).[81]

Lipomas

Lipomas often occur in the posterior neck, but they are rare in the pharynx.[82] When these arise in the pharynx, the

most common location is the aryepiglottic fold.[83] They are smooth, compressible, painless masses, although bulky ones may cause dysphagia or dyspnea and large retropharyngeal lipomas may compress the hypopharynx.[82, 83] Rare hibernomas have also been reported in the retropharyngeal region. On imaging, all of these fatty tumors can be diagnosed by their low CT density and their fatty MR signal characteristics.

UNKNOWN PRIMARY TUMORS

Patients with SCCA of the upper aerodigestive tract frequently present with cervical metastases.[84] The majority of these patients have an identifiable primary tumor. However, about 10% of patients have no visible lesion even after careful endoscopy and multiple blind biopsies. The diagnosis of metastatic SCCA is established by needle biopsy of the cervical adenopathy. These patients are considered to have an unknown primary tumor of the upper aerodigestive tract.

Treatment of patients believed to have an occult malignancy of the upper digestive tract varies from institution to institution. Most physicians favor wide-field external beam radiation to the nasopharynx, tonsil, tongue base, and pyriform sinus.[84, 85] Other physicians favor a more conservative approach consisting of a unilateral neck dissection and close observation to eventually identify a primary site.[86]

Identifying a primary cancer in a patient thought to have an occult or unknown tumor will alter the treatment plan. If the patient is to be treated with primary radiation, a wide-field radiation plan becomes more focused by applying a shrinking-field technique to the primary site. This change potentially increases the total dose delivered to the primary tumor from 5500 to 7440 cGy.[84] The concomitant reduction of the volume of tissue irradiated may decrease both the acute and chronic complications associated with radiation therapy. Thus, identification of a primary tumor site results in a higher and more localized tumor dose, reduces treatment morbidity, may increase local tumor control, and may lead to an increase in patient survival.

Detection of a clinically occult lesion is difficult for the otolaryngologist, radiation therapist, and radiologist. ''Blind'' endoscopic biopsies are often performed in locations known to be at high risk. Some centers perform an ipsilateral tonsillectomy, given the high incidence of occult lesions present in the palatine tonsil. Despite these efforts, the likelihood of detecting an occult lesion is only 20%.[84] One thing that has become clear in recent years is that if imaging is to help identify such an unknown tumor, it must be performed before any scoping or biopsy. If the imaging is performed before these clinical manipulations, any site of mucosal thickening is suspected of being a primary tumor and directed biopsies can be performed. If imaging is performed after scoping, hemorrhage and edema in the pharyngeal wall lessen the sensitivity of the study.

Imaging Findings

CT has been shown to be useful for detecting an unknown primary tumor and in experienced hands has a sensitivity of 37%.[87, 88] To obtain the maximum information from CT, the study must be of high quality and must be performed with 3-mm contiguous sections from the nasopharynx into the thoracic inlet. Metastases to level V nodes should suggest a nasopharyngeal lesion.[87] Historically the presence of large necrotic nodes has been associated with clinically occult tonsillar tumors.[84] Bilateral upper cervical lymph nodes suggest a lesion within the nasopharynx, tongue base, soft palate, supraglottic larynx, or pyriform sinus.[84] The main role of CT is to focus the endoscopic evaluation and guide the otolaryngologist so that a larger biopsy specimen can be

obtained from suspicious areas, thus potentially increasing the diagnostic yield over that of the limited and ''undirected'' speculative biopsies. Special attention should be paid to areas of asymmetric fullness ipsilateral to the side of nodal involvement. The precise role of MR imaging in detecting occult lesions has not yet been determined.

Recently, imaging with 2[F18] fluoro-2-deoxy-D-glucose (FDG) has shown promise in detecting occult primary lesions of the upper aerodigestive tract[87] (Fig. 28-58) (see Chapter 45).

NONNEOPLASTIC PROCESSES

Retropharyngeal Infections

A retropharyngeal space infection is a potentially life-threatening disease whose incidence has decreased in the antibiotic era. Historically, these infections were believed to occur almost exclusively in children less than 6 years of age.[89] However, with the increase in the immunocompromised patient population, these infections have become more frequent in adults, being more common in males than in females (2:1). Infections involving the retropharyngeal space usually result from an infection at a site whose primary lymphatic drainage is to the retropharyngeal lymph nodes. These sites include the sinonasal tract, throat, tonsil, oral cavity, and middle ear. Retropharyngeal infections also can result from a direct traumatic inoculation.[90, 91]

The anatomy of the retropharyngeal space is discussed in Chapter 34. This space extends from the skull base to the level of the carina, and its contents include fat and lymph nodes. The retropharyngeal lymph nodes are subdivided into lateral and medial groups.[12, 92, 93] The lateral group consists of one to three nodes situated just medial to the carotid sheath on the longus colli and longus capitus muscles, behind the posterior pharyngeal wall. These lymph nodes usually extend from the skull base to the level of C3. The medial group is inconstant and is located near the midline. When present, these nodes are usually found at the level of C2, although they may extend inferiorly as low as the vertebral body of C6. Most of the involved retropharyngeal nodes lie within 2 cm of the skull base. The afferent drainage of the retropharyngeal lymph nodes is from the nasopharynx, oropharynx, palate, nasal cavity, paranasal sinuses, middle ear, and eustachian tube, and the efferent drainage is to the level II nodes.

The danger space is situated dorsal to the retropharyngeal space between the alar and prevertebral fascia.[93] This space extends from the skull base to the level of the posterior diaphragm, and it is discussed in Chapter 34. Infections that involve the retropharyngeal space may enter the danger space and thus extend into the mediastinum.[93]

Patients with retropharyngeal space infections often present with fever, chills, odynophagia, sore throat, dysphagia, nausea, vomiting, respiratory distress, and neck pain and stiffness; these symptoms may suggest meningitis. On physical examination the patient may be drooling and diaphoretic, with bulging of the posterior nasopharyngeal/oropharyngeal wall.

Historically, a retropharyngeal space abscess was believed to be the ultimate result of efferent spread of infection to the retropharyngeal lymph nodes.[90] These nodes enlarged and underwent suppuration, eventually rupturing into the retropharyngeal space and creating an abscess. With the development of broad-spectrum antibiotics, the evolution of this disease has been slowed so that it is diagnosed and treated at an earlier stage, often before the development of a frank retropharyngeal abscess. That is, the treatment is directed to a suppurative (abscessed) node rather than to a retropharyngeal space abscess.

Today, a true retropharyngeal abscess is often the result of penetrating trauma to the oropharynx or nasopharynx. These abscesses also develop from a cervical spine osteomyelitis or diskitis or as a complication of spinal surgery.[89] The treatment is surgical drainage, either by an intraoral or open procedure, depending on the size of the lesion and the clinical stability of the patient.

As mentioned, currently retropharyngeal infections are often diagnosed before the formation of a true retropharyngeal abscess. Recent experience suggests that a retropharyn-

Copyright © 2003, Mosby, Inc. All rights reserved.

geal suppurative adenitis, diagnosed on either CT or MR imaging, may be successfully managed with antibiotics, without the need for surgical exploration and drainage.[94]

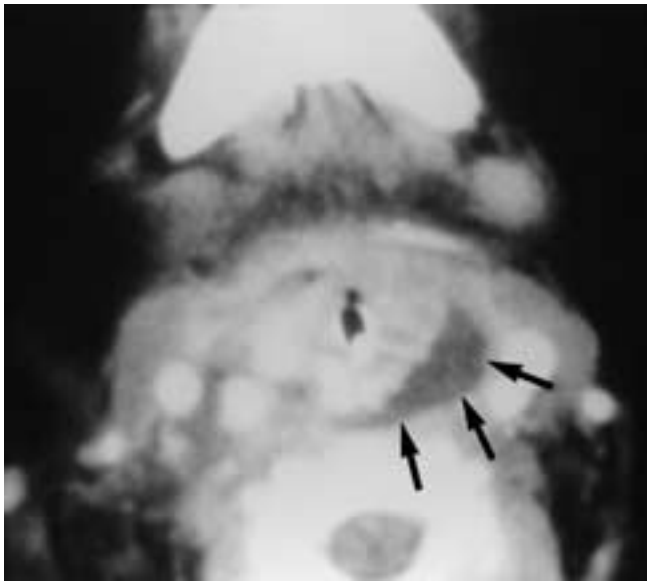
The ability to medically manage a retropharyngeal abscess successfully appears to be the result of both early sectional imaging and the use of effective antibiotic therapy. Historically, no more than 10% to 15% of these infections resolved with medical therapy alone. Recent reports suggest that 40% to 50% of patients can be successfully treated without surgical drainage.[89]

Imaging Features

The initial diagnostic imaging evaluation of a patient suspected of having a retropharyngeal space infection usually consists of a lateral plain film of the neck, taken during quiet breathing with the head in a neutral position. The presence of prevertebral swelling (in adults, usually more than one half of the AP diameter of C4), the loss of the normal cervical lordosis, and air in the prevertebral soft tissues are all findings suggestive of an underlying infection. However, plain films alone usually cannot determine the exact location and the extent of the process.

CT and MR imaging permit accurate localization of infections involving the deep neck and help distinguish between suppurative retropharyngeal adenitis with associated retropharyngeal space edema and a true retropharyngeal abscess. CT is the preferred modality because of its high resolution, shorter scan times, lower costs, and overall better evaluation of nodal disease. The reduction in scan time with CT is especially advantageous in the pediatric population and may reduce or eliminate the need for sedation in infants and young children.

A retropharyngeal abscess appears as a low-attenuation region expanding the retropharyngeal space, with enhancement along the margins of the space. There often is an associated significant mass effect, and the posterior pharyngeal wall may be quite displaced ventrally[93] (Fig. 28-59). Air may occasionally be seen within the abscess (Fig. 28-60). Abscesses resulting from an adjacent diskitis are contiguous with the adjacent disk space and are associated with erosion of the neighboring vertebral body endplates (Fig. 28-61).



VIEW IMAGE

FIGURE 28-59 Axial contrast-enhanced CT scan shows a fluid collection in the retropharyngeal space (*arrows*). The lack of a thick, enhancing wall does not exclude a retropharyngeal abscess and, in our experience, an enhancing wall is rarely present in a retropharyngeal space abscess.

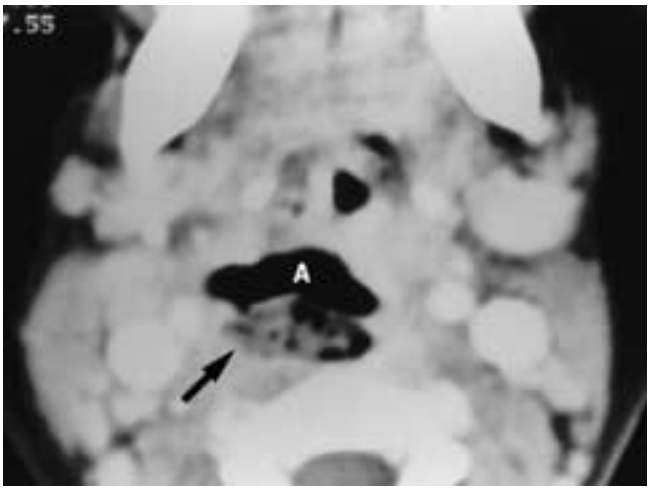


FIGURE 28-60 Axial contrast-enhanced CT scan shows a retropharyngeal abscess containing fluid and air (*arrow*). *A*, Normal airway of the oropharynx.

VIEW IMAGE

Suppurative retropharyngeal adenitis is characterized by an enlarged retropharyngeal lymph node that contains a low-attenuation center with an enhancing rim (Fig. 28-62).[93, 94] The low-attenuation center does not necessarily imply the presence of actual pus, as the same CT appearance is present in lymph nodes containing early liquefaction (presuppurative phase) and in those that have undergone complete liquefaction necrosis (suppurative phase). Suppurative retropharyngeal adenitis is often associated with edema, which is characterized by a smooth expansion of the retropharyngeal space with ''mucoid'' density material (10 to 25 HU). However, there is no enhancement of the margins of the retropharyngeal space, which differentiates a suppurative adenitis from a retropharyngeal abscess.

Previous reports have shown that ultrasound may be used to differentiate solid lesions from complex fluid collections located within the retropharyngeal region.[95] However, ultrasound is often unable to determine whether these collections are within enlarged lymph nodes or involve the entire retropharyngeal space. For this reason, if ultrasound is the only imaging modality, surgical intervention has been recommended in all of these cases. CT and MR imaging permit localization of areas of liquefaction and in most cases allow accurate differentiation between suppurative adenitis and retropharyngeal abscess.

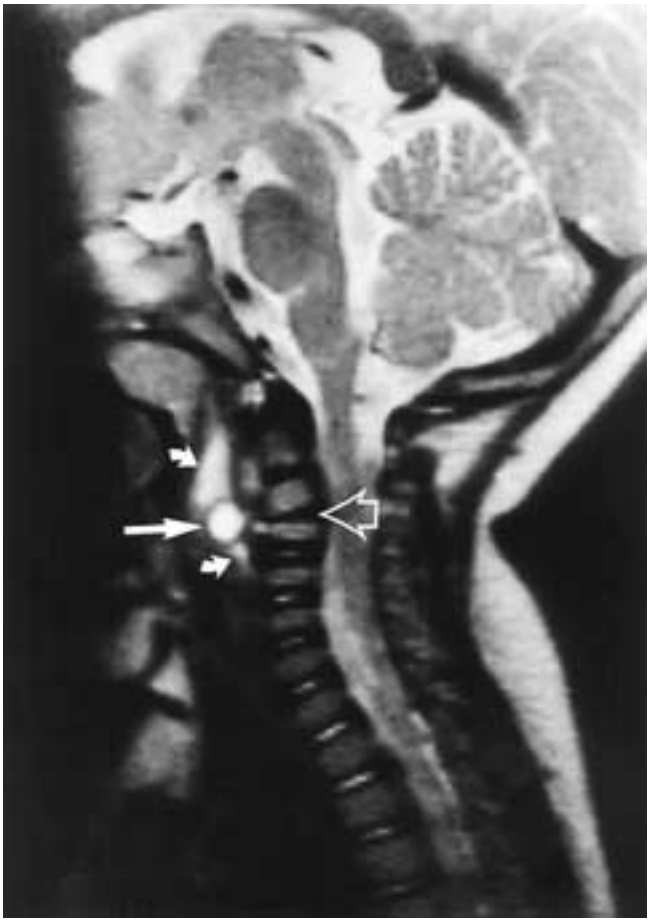
Peritonsillar Abscesses

Acute tonsillitis is usually a self-limited febrile disease of adolescents or young adults. The most common offending bacterial organisms include beta-hemolytic streptococcus,

Copyright © 2003, Mosby, Inc. All rights reserved.

staphylococcus, pneumococcus, and hemophilus. Suppurative uncontrolled infection of the tonsils may result in a peritonsillar abscess (quinsy) or, rarely, in a tonsillar abscess. A peritonsillar abscess is an accumulation of pus around the palatine tonsils, and if this abscess extends outside the tonsillar fossa, it may involve the lateral retropharyngeal or parapharyngeal spaces. A severe sore throat and pharyngeal edema that progress despite antibiotic therapy are the usual clinical presentations of such an abscess. Trismus develops if the medial pterygoid muscle is involved.

On CT, the appearance of acute or chronic tonsillitis is nonspecific, and the focal homogeneous swelling of the palatine tonsil may simulate a tumor[93] (Fig. 28-63). The inflammatory process may extend laterally into the parapharyngeal space, medial pterygoid muscle and masticator space, and soft palate. If a frank abscess is present, there is a low-attenuation central region surrounded by an enhanced rim in the peritonsillar or tonsillar region (Figs. 28-64 and 28-65). The abscess may also extend from the tonsillar bed into the retropharyngeal and submandibular spaces.[96]



VIEW IMAGE

VIEW IMAGE

Acute Calcific Prevertebral Tendinitis (Tendinitis of the Longus Colli)

Acute calcific prevertebral tendinitis is an idiopathic noninfectious inflammation that can be confused with retropharyngeal abscess.[97] Other names for this uncommon disease include tendinitis of the longus colli and retropharyngeal calcific tendinitis. There is inflammation of the tendinous insertion of the longus colli muscle with deposition of calcium hydroxyapatite crystals. The oblique fibers of the muscle are involved. An effusion can extend from the prevertebral space into the retropharyngeal space. The presentation can mimic that of retropharyngeal abscess, but the patient is less febrile and may have a normal white blood cell count.

CT shows calcific density in the region of the insertion of the longus colli muscle just anterior to the upper cervical spine (Fig. 28-66). An effusion extends into the retropharyngeal space and is seen in a typical pattern extending from C1 down to the level of C5 or C6. The abnormality begins in the prevertebral space rather than in the retropharyngeal space, so the edema or fluid collection may surround part of the muscle, particularly superiorly.

MR imaging shows the extent of the disease and the tapering of the effusion. The calcification is less obvious, but

the relationship of the fluid collection to the muscle may be easier to appreciate, particularly on T2-weighted images.

Recognition of the imaging appearance is important, as this illness is self-limited and responds to either steroids or nonsteroidal anti-inflammatory drugs. It is not an infection, and surgery to drain the collection is of no benefit.

Tornwaldt's Cysts

Tornwaldt's cyst is a benign developmental lesion within the midline nasopharynx. Its incidence at autopsy is 4%, the peak age of presentation is 15 to 30 years, and there is no sex predilection. The development of Tornwaldt's cyst is related to the embryogenesis of the notochord. In the early embryo, before the notochord reaches the prechordal plate, it comes into contact with the endoderm of the primitive pharynx. At this level, a small outpouching of the pharyngeal mucosa develops, directed toward the brain. Some believe that this outpouching is related to Seessel's pouch, which contributes to the preoral gut.[3] If a focal adhesion develops between the notochord and this endoderm, when the notochord ascends back to the level of the developing skull base, a small portion of the nasopharyngeal mucosa is carried along it. This results in the creation of a midline diverticulum that in the adult is lined by normal pharyngeal mucosa. When the patient develops a pharyngitis, the orifice of this diverticulum swells and closes, and a cyst is formed. The cyst contents typically have a high protein content and are infected with anaerobic bacteria. In this state, Tornwaldt's cysts are usually asymptomatic, incidental imaging findings. Periodically, the pressure within the cysts increases and overcomes the relative stenosis at the orifice. This releases anaerobic secretions into the nasopharynx, and the patient complains of periodic halitosis. Asymptomatic cysts require no treatment, but symptomatic lesions are drained via an intraoral approach.

Imaging Features

On MR imaging, a Tornwaldt's cyst appears as a well-delineated, thin-walled, midline cystic lesion that usually varies between 2 and 10 mm in diameter. The signal

VIEW IMAGE

characteristics vary, as does the protein content of the cyst. The T1-weighted signal intensity can be either low or high, and the T2-weighted signal intensity is high (Figs. 28-67 and 28-68). There usually is no enhancement with contrast. On CT, these cysts present as midline nasopharyngeal cysts with mucoid attenuation located between the longus colli muscles. If the cyst contains a high protein content, the resulting increased density may on occasion mimic a soft-tissue mass (Fig. 28-68). In patients with prominent adenoids, these cysts may be difficult to identify.

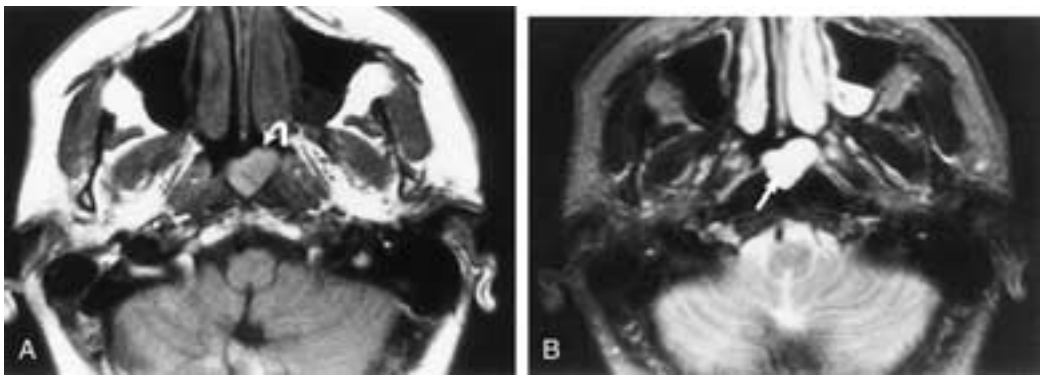

FIGURE 28-67 **A**, Axial T1-weighted noncontrast MR image shows a well-delineated lesion (*arrow*) with increased signal intensity located within the nasopharynx. FIGURE 28-68 Tornwaldt's cyst. **A**, CT scan through the upper nasopharynx demonstrates a midline Tornwaldt's cyst (*arrows*). Note that its density is similar to that of the surrounding muscle. The high density of this cyst is probably related to its high protein concentration. **B**, Sagittal T1-weighted MR scan through the upper nasopharynx demonstrates a high signal intensity Tornwaldt's cyst (*c*). The high intensity is due to the high protein concentration within the cyst. This shortens the T1 relaxation time sufficiently to produce increase in intensity on T1-weighted images.

Adenoidal Hypertrophies

Adenoids, or nasopharyngeal tonsils, are located in the roof of the nasopharynx. They start to become prominent by age 2 to 3 years, often filling the entire nasopharynx and extending into the posterior choanae. Regression starts in early adolescence and continues into later life. Most people have little if any identifiable adenoidal tissue by age 30 to 40 years. However, normal adenoids can occasionally be identified in patients 50 to 60 years old. Conversely, if no adenoidal tissue is seen in a young child, the possibility of an immune deficiency syndrome should be considered. Prominent adenoidal tissue in adults should raise the possibility of HIV disease.[10]

On CT, adenoids appear as homogeneous, superficial soft tissue filling the superior and upper lateral recesses of the nasopharynx. The adenoids have an attenuation similar to that of muscle, and small superficial cysts and calcifications are often present. After contrast administration, a thin, enhancing line is often seen along the deep surface of the adenoids. This mucosal venous and pharyngobasilar enhancement should be present and intact, as violation of this line indicates the presence of an aggressive mass in the nasopharyngeal roof. On MR imaging, the adenoids have a T1-weighted signal intensity similar to that of muscle; however, they have a high T2-weighted signal intensity, which distinguishes them from muscle (Fig. 28-69). Unfortunately, the signal intensities of the adenoids are similar to those of lymphoma and most cellular tumors, and distinction between normal lymphoid tissue and tumor may be impossible on CT and MR imaging.[98] Endoscopy with biopsy is the only way to definitively make this distinction. Reactive cervical adenopathy often accompanies prominent adenoidal tissue in children, but it can also be seen in HIV-infected patients and in patients with nasopharyngeal lymphoma.

Acquired Immunodeficiency Syndrome

Acquired immunodeficiency syndrome (AIDS) is caused by human T-cell lymphotrophic virus type III (HTLVIII) and is a potentially devastating disease of childhood and adulthood.[99] Opportunistic infections and certain malignancies have been identified in up to 50% of patients with AIDS.[99–101] A variety of infections involving the oral cavity and oropharynx have been described in AIDS patients, including fungal diseases such as oral candidiasis, cryptococcosis, and histoplasmosis; bacterial infections, including those caused by *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*; and herpes simplex infections, which require treatment with oral acyclovir or intravenous foscarnet (Fig. 28-70).[101, 102] Hairy cell leukoplakia is a manifestation of Epstein-Barr virus and presents as a white plaque most often seen on the lateral margin of the tongue.

The typical immunocompetent patient with a pharyngitis usually does not undergo CT or MR imaging. The diagnosis is established clinically and by cultures. However, the immunocompromised patient with pharyngitis may have an opportunistic infection such as candida or cytomegalic virus, with involvement of the hypopharynx and esophagus. In these patients, occasional imaging is performed with the goal of mapping the disease and establishing the presence or absence of an associated abscess.

A variety of neoplasms have been reported to have a tendency to occur in AIDS patients. Because of their rarity in the general population, in the proper clinical setting these neoplasms are considered AIDS-defining malignancies.[99] These malignancies include Kaposi's sarcoma and small noncleaved B-cell (Burkitt's, non-Burkitt's) and large B-cell (immunoblastic) NHL (Fig. 28-71). Involvement of the oropharynx has been reported in up to 20% of patients with cutaneous Kaposi's sarcoma, although any portion of the upper

aerodigestive tract may be involved (Fig. 28-72).[103, 104] Clinically, these tumors may present as either small, violaceous nodules or lobulated masses that measure several centimeters in diameter. Lymphoma preferentially involves the adenoidal and palatine tonsillar lymphoid tissues, and early nasopharyngeal lesions may mimic the diffuse adenoidal hypertrophy typically seen in immunocompromised hosts.[105, 106] Large lymphomas may extend into the cavernous sinus, usually along neurovascular channels. On imaging, skull base erosion is rarely demonstrated[99] (Fig. 28-73). The clinical symptoms often reflect the location of the tumor and include dysphagia and airway obstruction.

VIEW IMAGE

FIGURE 28-74 Axial contrast-enhanced CT scan demonstrates a soft-tissue mass situated in the left tonsil (*straight arrows*) associated with edema in the retropharyngeal space (*curved arrows*). The patient was involved in a motor vehicle accident, and the lesion was due to a hematoma located within the tonsillar fossa.

In an adult, the triad of increased adenoidal tissue, parotid cysts (lymphoepithelial cysts), and diffuse cervical lymph adenopathy is highly suggestive of HIV infection. However, since the advent of effective chemotherapy, the prominent adenoids and cervical adenopathy need not be present in these patients.

Advanced SCCA have recently been reported in patients under the age of 45 years. In many of these patients, the typical risk factors of smoking and alcohol abuse were not present. It is unclear whether there is an increased incidence of SCCA in patients with HIV infection. However, it appears that these tumors are more aggressive, and the prognosis of these patients tends to be worse.[107]

TRAUMA

Pharyngeal trauma may be due to blunt trauma, such as that experienced in a motor vehicle accident, and may result in mucosal and retropharyngeal hematomas (Fig. 28-74). Hematoma of the hypopharynx may also be iatrogenic, either from instrumentation (Fig. 28-75) or from a foreign body such as a chicken bone. Rarely, retropharyngeal hematomas have occurred after minor trauma in hemophiliac patients. The high CT attenuation of a hematoma usually allows the diagnosis to be suggested (Fig. 28-75A).

Penetrating trauma can cause perforation of the pharyngeal wall, resulting in a direct communication between the oral cavity and the retropharyngeal space. Persistent communication results in large amounts of air tracking throughout the deep fascial planes (Fig. 28-76). This communication provides a direct route for spread of organisms that normally colonize the oral cavity, allowing them to enter the deep neck and place the patient at high risk of developing a retropharyngeal abscess, fasciitis, and even mediastinitis.

VIEW IMAGE

FIGURE 28-75 **A**, Axial CT scan without contrast shows a large, hyperdense intramural hematoma of the hypopharynx. The patient had been anticoagulated and then required emergency intubation. The nasogastric tube (*n*) is in the right hypopharynx. **B**, Axial CT scan shows a large postcricoid mass (*m*) thought to be carcinoma clinically and radiographically. Biopsy showed acute and chronic inflammation and granulation tissue in a patient who had been intubated for long periods of time. There is a small amount of air in the appendix of the left laryngeal ventricle (*arrow*). **C**, Axial CT scan with contrast shows diffuse edema secondary to radiation therapy. The aryepiglottic folds are thick (*a*), the subcutaneous fat is streaky (*thin, straight arrows*), and the platysma muscle (*curved arrow*) and the skin (*open arrows*) are thick.

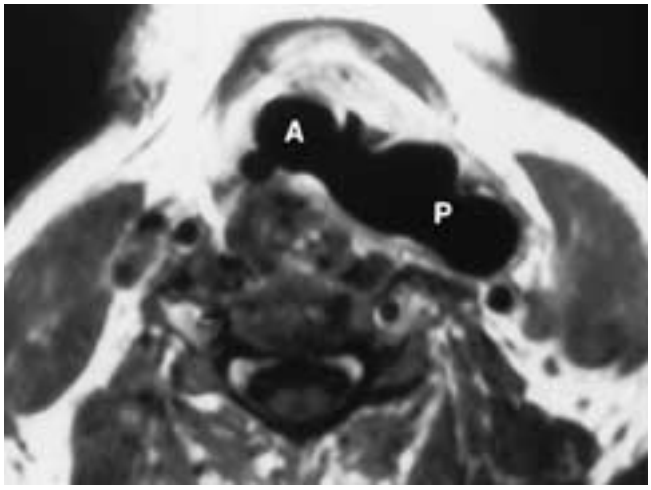
MISCELLANEOUS LESIONS

A tortuous internal carotid artery and/or common carotid artery may swing behind the posterior wall of the oropharynx and hypopharynx, respectively, causing a pulsating submucosal bulge that is apparent on clinical inspection. Before the CT and MR imaging era, this abnormality was considered rare. However, presently this abnormality is considered relatively common, often occurring as an incidental finding on scans. Imaging is important to identify the etiology of this diagnosis, thus stopping an unnecessary and dangerous biopsy.



VIEW IMAGE

FIGURE 28-77 Axial noncontrast T1-weighted MR image shows marked dilatation of the lateral wall of the pharynx which is characteristic of a pharyngocele (*P*). Note the normal appearance of the airway (*A*).

A pharyngocele is a benign outpouching of the pharyngeal mucosa of the upper pyriform sinus. A frontal barium swallow film best shows the pharyngocele, which fills with barium as a broad-based outpouching (Fig. 28-77). These pharyngoceles distend on phonation and with Valsalva maneuvers. An air-filled pharyngocele can occasionally be seen on CT or MR imaging as an incidental finding (Fig. 28-77). Zenker's diverticulum is a mucosa-lined outpouching of the hypopharynx (Figs. 28-78 and 28-79). Dyssynergy of the cricopharyngeus muscle seems to play a role in the formation of this pulsion diverticulum.[18] Because this muscle fails to relax as a bolus passes, a high ''upstream'' pressure is created, thus contributing to the development of this diverticulum. Zenker's diverticulum protrudes through Killian's dehiscence and extends posteriorly and often laterally, usually to the left side.[18]

On a barium swallow, during maximum relaxation of the cricopharyngeus, normally no posterior submucosal mass should be seen that identifies the level of the cricopharyngeus. If such an impression is identified, it suggests dyssynergy or cricopharyngeal spasm (Fig. 28-80).

Posterior submucosal impressions on the barium column can result from osteophytes or rare anterior bulging of intervertebral disks. Interestingly, even exuberant anterior osteophytes rarely cause dysphagia unless there is a concomitant reason to limit the range of motion of the larynx (prior surgery, irradiation, etc.). A prominent lobe of the thyroid gland may occasionally cause an extrinsic mass on the anterolateral pharyngeal barium column, especially in older patients. It must be also noted that often symptoms of dysphagia reflect a hiatal hernia with reflux.

A retention cyst of a minor salivary gland is a small, superficial mass that can occur virtually anywhere in the pharynx and supraglottic larynx. Its CT fluid density and MR signal intensities are fairly diagnostic. The appearance is similar to that of retention cysts elsewhere in the pharynx.

''Crack'' cocaine burns of the larynx and hypopharynx may result in granulation tissue. The imaging findings may mimic those of carcinoma, both clinically and radiographically, and the patient may not volunteer the history that would help establish the correct diagnosis.[108] Biopsy is usually necessary to differentiate between granulation tissue and carcinoma.

In a patient with a paralyzed vocal cord or unilateral vagal paralysis, the ipsilateral pyriform sinus may be large. This appearance is described in Chapter 30.

POSTTREATMENT PHARYNX

Radiation Therapy

Radiation therapy (RT) has proven to be an effective modality for the treatment of a variety of laryngeal and pharyngeal carcinomas, with local control rates similar to those achieved with surgery.[109–114] RT is being given to patients as the preferred treatment, as well as to patients who

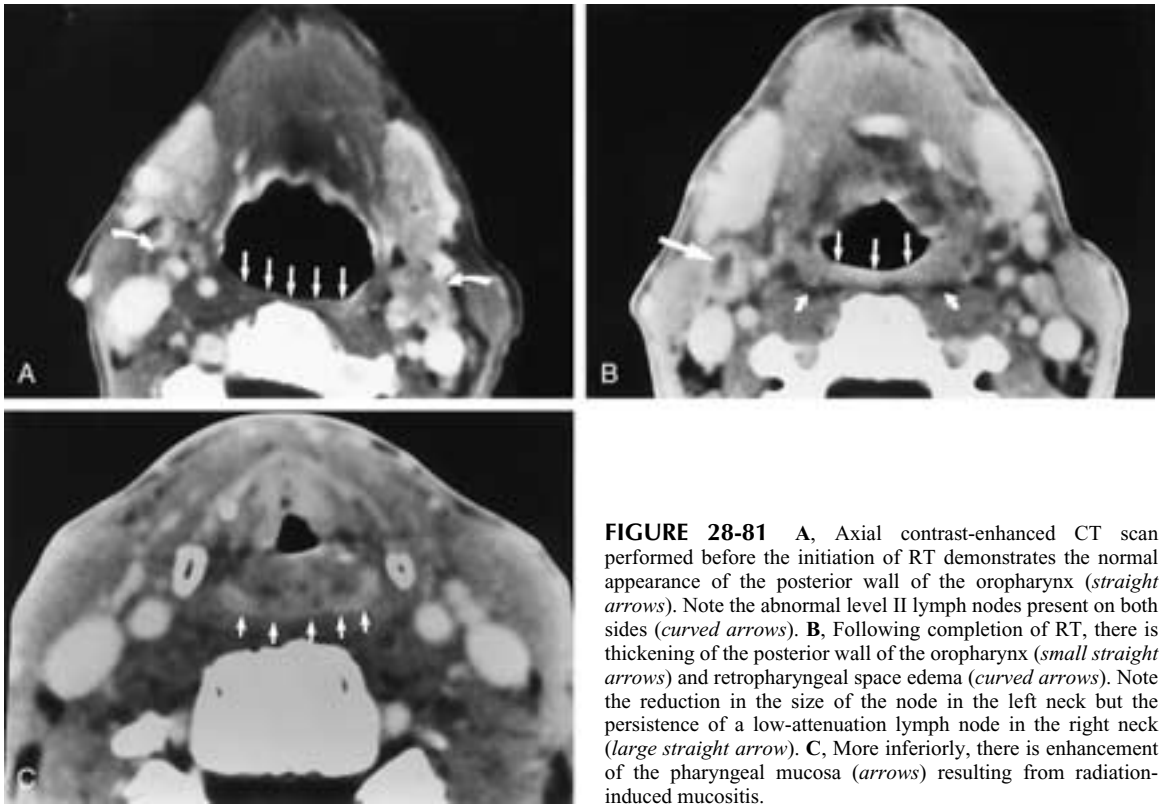
refuse surgery or who are poor surgical candidates because of underlying medical conditions.

Histologically, RT results early on in an acute inflammatory reaction within the deep connective tissues characterized by leukocytic infiltration, histiocyte formation, necrosis, and hemorrhage.[114–119] Detachment of the endothelial cells lining small arteries, veins, and lymphatics causes increased permeability, resulting in interstitial edema. Within 1 to 4 months after RT, there is deposition of rich collagenous fibers, with sclerosis and hyalinosis of the connective tissues. This inflammatory process eventually results in the obstruction of small arteries, veins, and lymphatics. By 8 months, there is advanced sclerosis, hyalinosis, and fragmentation of the collagen fibers within the connective tissues. Eventually there may be a reduction in interstitial fluid resulting from the formation of collateral neocapillary and lymphatic channels.[115, 118] The extent of the observed changes in the area included within the radiation port is mainly dependent on the total dose; however, more advanced and persistent changes may be seen in patients who continue to smoke after RT.

The pharynx is subjected to a high dose of radiation during definitive treatment of cancers and subsequently undergoes predictable changes that should not be confused with those of tumor. Pharyngeal changes resulting from RT include increased enhancement of the pharyngeal mucosa, which is thought to be due to the formation of telangiectatic vessels that may arise as a sequela of the radiation-induced mucositis.[118] The posterior pharyngeal wall typically thickens from a normal 2 to 3 mm to 6 to 7 mm in the post-RT patient. Additionally, patients typically develop 3 to 5 mm of edema in the retropharyngeal space (Fig. 28-81). These reactive changes may persist for many months or years.[118]

As has been previously reported for laryngeal tumors, successfully treated pharyngeal tumors result in a reduction in primary lesion size (Fig. 28-82).[119] However, the diffuse



VIEW IMAGE

FIGURE 28-81 **A**, Axial contrast-enhanced CT scan performed before the initiation of RT demonstrates the normal appearance of the posterior wall of the oropharynx (*straight arrows*). Note the abnormal level II lymph nodes present on both sides (*curved arrows*). **B**, Following completion of RT, there is thickening of the posterior wall of the oropharynx (*small straight arrows*) and retropharyngeal space edema (*curved arrows*). Note the reduction in the size of the node in the left neck but the persistence of a low-attenuation lymph node in the right neck (*large straight arrow*). **C**, More inferiorly, there is enhancement of the pharyngeal mucosa (*arrows*) resulting from radiation-induced mucositis.

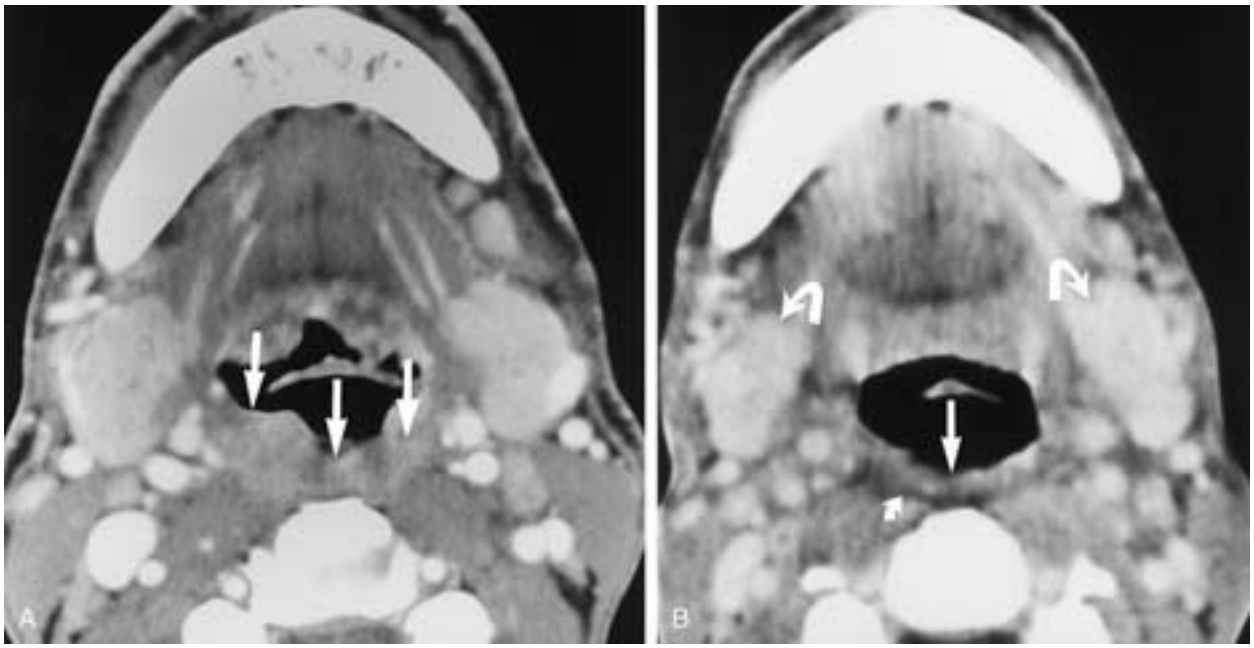
FIGURE 28-82 **A**, Axial pretreatment, contrast-enhanced CT scan demonstrates a large right tonsillar carcinoma. The mass extends laterally to involve the parapharyngeal space and invades the medial pterygoid muscle. The mass extends posteriorly to involve the carotid space. **B**, Following combined chemotherapy and RT, there is a marked reduction in the size and enhancement of the mass. This patient had no evidence of recurrent disease 2 years following completion of treatment.

and residual changes occurring in the pharynx should not be confused with residual tumor (Figs. 28-82 and 28-83). Comparing a present imaging study with a prior examination is the best method for making this distinction. Soft-tissue thickening caused by RT will not progressively enlarge, and any such progressive change should be suspected of representing tumor. In addition, the edematous changes tend to have an attenuation less than that of muscle, whereas tumor has a similar attenuation to that of muscle. Potential pharyngeal and laryngeal complications following RT



VIEW IMAGE

FIGURE 28-83 **A**, Axial contrast-enhanced CT scan demonstrates a tumor involving the posterior wall of the oropharynx (*arrows*) with bilateral nodal disease. **B**, Following RT, there is a marked reduction in the size of the tumor, with residual thickening of the posterior wall of the oropharynx (*straight arrow*). Retropharyngeal space edema (*small curved arrow*) and mild atrophy of the submandibular glands (*large curved arrows*) are normal changes resulting from RT.

include laryngeal necrosis, pharyngocutaneous fistula, pharyngeal stenosis, and peripheral nerve paralysis.[120]

Surgery

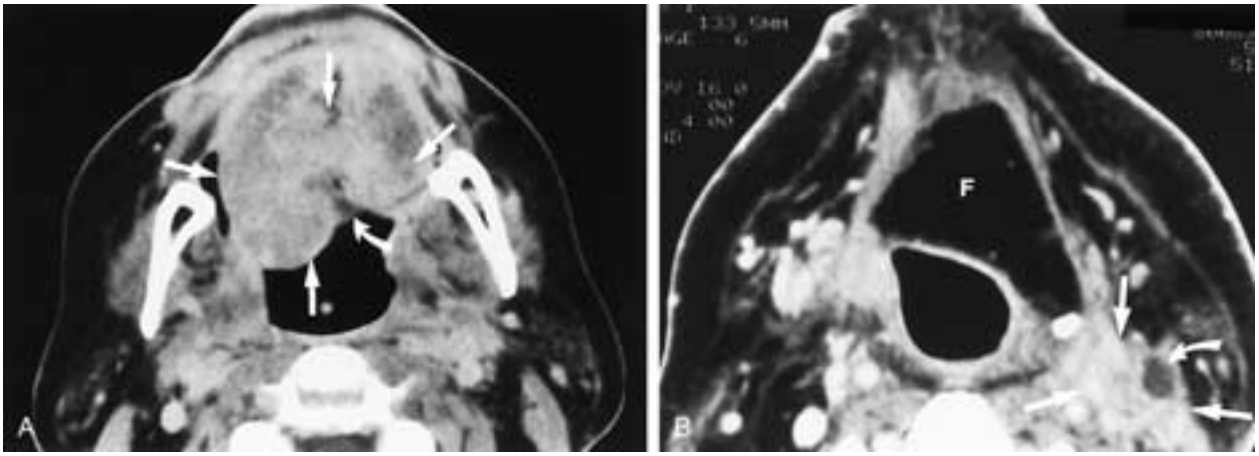
A variety of surgical procedures are available for treatment of malignancies involving the upper aerodigestive tract. However, resection results in marked distortion of the underlying anatomy, making interpretation of postoperative imaging studies difficult. The postoperative pharyngeal wall is typically thin and smooth (Fig. 28-84).

A variety of reconstruction procedures have been developed that utilize either myocutaneous flaps or free flaps.[121] This topic is discussed further in Chapter 43. When a myocutaneous flap is used, the resulting imaging picture characteristically shows the thin, rotated mucosal surface overlying the fatty bulk of the flap (Fig. 28-85).

The postsurgical neck is difficult to evaluate because of the extensive anatomic alterations caused by the resection. Because granulation and scar tissue normally enhance, the presence of contrast enhancement on CT or MR imaging does not help differentiate tumor from postoperative change. However, if an area that has reduced T1-weighted signal intensity progressively loses signal intensity on proton density and T2-weighted images, it is likely to be fibrosis rather than tumor.

As mentioned, comparison with a baseline posttreatment CT or MR study is often the best way to evaluate recurrent disease. Recurrent tumor should be considered when there is progressive enlargement of a node or a mass within the original primary site or along the margins of the surgical resection.[122–124] If prior studies are unavailable, the most reliable signs of recurrent disease are the presence of an obvious enhancing mass at the primary site or an obviously positive lymph node, as seen on CT. Tumor invasion of the internal carotid artery is difficult to diagnose on CT and MR imaging unless there is obvious narrowing of the vessel caliber (Fig. 28-52). This topic is discussed in Chapters 36 and 43.

Because tumors are more metabolically active than nontumorous surrounding tissue, measurement of the metabolic activity of a potential tumor recurrence may be more beneficial than pure morphologic analysis. Modalities



VIEW IMAGE

FIGURE 28-85 **A**, Axial CT scan obtained through the tongue base shows a large, ulcerated mass invading and replacing the tongue base (*straight arrows*, tumor; *curved arrow*, ulceration. **B**, This patient underwent a total glossectomy and myocutaneous flap reconstruction. The flap (*F*) fills in the operative defect and provides a mucosal surface to the pharynx. Note the low-attenuation lymph node (*curved arrow*) and the surrounding soft-tissue mass (*straight arrows*) indicating recurrent disease.

that can evaluate metabolic activity such as FDG and thallium-201, as well as MR spectroscopy, are currently being investigated (Fig. 28-53).[125–128] These topics are discussed in Chapter 45.

EMBRYOLOGY

The face and neck are formed primarily by the paired pharyngeal or branchial arches. A detailed discussion of facial embryology is given in Chapter 1, and a thorough review of neck embryology is presented in Chapter 33. The reader is referred to these chapters for information on these subjects. With specific reference to lesions or abnormalities that can encroach upon the airway, the following areas are briefly reviewed.

FACE AND NASOLACRIMAL DUCTS

The facial prominences appear at the end of the fourth week of fetal development, and these structures are derived mainly from the first pair of pharyngeal arches (Fig. 29-1). The stomodeum forms the center of the developing face and, relative to the stomodeum, the mandibular prominences are caudal, the maxillary prominences are lateral, and the frontonasal prominence is cranial. The nasal placodes originate lateral to the frontonasal prominence under inductive influence from the ventral portion of the forebrain.[1, 2] During the fifth week the nasal placodes invaginate to form nasal pits, which are surrounded by ridges of tissue called the medial and lateral nasal prominences. Medial growth of the maxillary processes compresses the medial nasal prominences toward the midline. These structures fuse to form the upper lip. The four upper incisor teeth, the medial superior alveolar ridge, and the primary palate originate as the *intermaxillary segment* from the medial nasal prominences.[2] The mandibular prominences form the lower lip and jaw.

The nasolacrimal groove is a deep furrow between the maxillary and lateral nasal prominences. This groove detaches from the overlying ectoderm and ultimately canalizes to form the nasolacrimal duct and sac. The nasolacrimal duct runs from the medial canthus of the orbit to the inferior meatus of the nasal cavity. The maxillary prominences form the cheeks and maxillae and fuse with the lateral nasal prominences over the developing nasolacrimal duct. The nose is formed from the frontal prominence (bridge), the medial nasal prominences (crest and tip), and the lateral nasal prominences (alae).

PALATE

The triangular primary palate develops from the intermaxillary segment and is located anterior to the midline incisive foramen. The secondary palate (hard and soft palates) arises as two palatal shelves from the maxillary prominences (Fig. 29-2).

NASAL CAVITIES

The formation of the nasal cavity depends mainly on the inferior migration of the primitive nasal septum and the

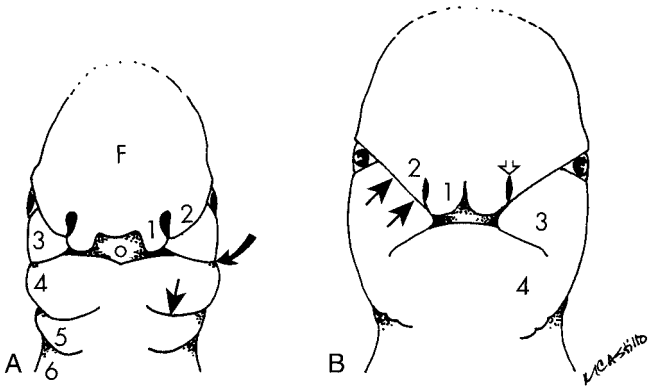

FIGURE 29-1 Development of the face. **A**, Frontal drawing of a 5-week-old fetus shows the oral placode (*o*), which divides the face into superior and inferior compartments. Superiorly and centrally is the massive frontal eminence (*F*). The medial nasal prominence (*1*) is separated from the lateral nasal prominence (*2*) by the nasal pit. The nasooptic groove separates the lateral nasal prominence from the maxillary process (*3*). The inferior compartment of the face is formed by the mandibular arch (*4*) which is separated from the lower hyoid arch (*5*) by the hypomandibular cleft (*arrow*). The third branchial arch (*6*) is present inferiorly. The curved arrow indicates the position of the ear tubercules. **B**, Frontal drawing of a 7-week-old fetus shows that the face has acquired a more recognizable pattern. The medial nasal (*1*) and lateral nasal (*2*) processes are separated by the rudimentary nostril (*open arrow*) and are delineated laterally by the nasal ala. The midface consists mainly of the maxillary process (*3*) on either side. The inferior face is formed by the two mandibular processes (*4*). The orbits are better developed and have migrated inferiorly and medially to a more midline position. The nasooptic grooves (*small arrows*) deepen and eventually canalize to form the nasolacrimal ducts.

FIGURE 29-2 Development of the palate and nasal cavity. **A**, Drawing of a coronal view of a 6-week-old fetus shows that the oral (*o*) and nasal (*n*) cavities communicate with each other. The superior nasal cavity is divided by the midline septum (*s*), which contains cartilage (*shaded area*). The palatal shelves (*p*) are short and are located posterior to the primary palate. The palatal shelves are separated by a space that contains a relatively large tongue (*T*). **B**, Drawing of a coronal view of an 8-week-old fetus shows that the nasal septum (*s*) has elongated and extended inferiorly. The rudimentary nasal (*n*) and oral (*o*) cavities remain joined. The palatal shelves (*p*) are larger and begin to migrate medially. The tongue (*T*) is relatively smaller. **C**, Drawing of a coronal view of a 10-week-old fetus shows that the palatal shelves (*p*) and the inferior border of the nasal septum (*s*) have fused, creating a separation between both nasal cavities (*n*) and the oral (*o*) cavity. The tongue (*T*) is now confined to the oral cavity. Rudimentary nasal conchae (*) are present. The configuration of this region now approximates that of the adult.

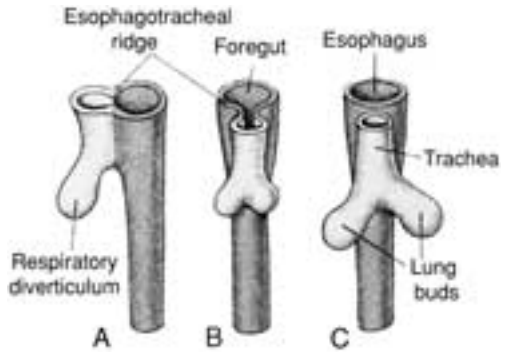
medial migration of the palatal shelves (Fig. 29-2). Development of the nasal cavity progresses with deepening of the nasal pits. The oronasal membrane separates the pits from the primitive oral cavity. The primitive choanae are foramina in the oronasal membrane located on either side of the midline immediately behind the primary palate. With the subsequent formation of the secondary palate, the definitive choanae form at the junction of the nasal cavity with the pharynx.

PHARYNX, LARYNX, AND TRACHEA

The respiratory primordium begins at about the fourth week of gestation with the formation of the laryngotracheal groove. As this groove evaginates, it forms a pouch-like laryngotracheal diverticulum located ventral to the caudal part of the developing foregut. Longitudinal folds develop from caudal to rostral on either side of the diverticulum and ultimately fuse to form the tracheoesophageal septum that separates the respiratory system from the esophagus (Fig. 29-3). Abnormalities in partitioning of the esophagus and trachea result in esophageal atresia, with or without tracheoesophageal fistula. The primitive laryngotracheal tube arises from gradual elongation of the diverticulum. The distal end of the tube eventually develops into the lung buds, and the proximal end forms the primitive laryngeal aditus.[1]

The larynx develops from the proximal end of the laryngotracheal tube. The arytenoid swellings develop at the cranial end of the laryngotracheal tube, and these two lateral swellings grow cranially and medially to produce the T-shaped slit of the laryngeal aditus (Fig. 29-4).[1] The laryngeal lumen becomes temporarily occluded at 8 weeks of gestation as a result of epithelial proliferation. If normal recanalization does not occur during the tenth gestational week, a laryngeal web results. The laryngeal ventricles form during recanalization of the larynx. These recesses are bounded by folds of mucous membrane that become the vocal folds (cords) and vestibular folds (false cords).[3] Failure of separation of the vocal folds results in congenital atresia of the larynx. This rare anomaly results in the congenital high airway obstruction syndrome (CHAOS).[4]

The thyroid cartilage develops from the fourth arch as two lateral plates that fuse in the midline. This process is nearly complete by the ninth gestational week. The cricoid



VIEW IMAGE

cartilage begins as two cartilaginous centers of the sixth arch. First, the centers grow and unite in the ventral midline; then, by the seventh gestational week, they fuse dorsally. The rostral advancement of the tracheoesophageal septum results in the fusion of the dorsal cricoid lamina. At first the cricoid lumen is slit-like in shape, but eventually the ventral and lateral walls of the cricoid cartilage condense, and there is progressive enlargement of the lumen. Failure of this condensation process results in congenital subglottic stenosis. The arytenoid cartilages are initially fused to the cricoid cartilage but eventually separate from it and form the cricoarytenoid joints.

GREAT VESSELS

The embryology of the great vessels is reviewed in Chapter 33. Errors in this embryologic process may result in aberrant vessels that can cause impressions on the trachea (Fig. 29-5). Of particular note are the following two situations: the persistence of the entire right dorsal aorta, which results in a double aortic arch forming a complete vascular ring, and incomplete obliteration of the proximal right dorsal aortic arch with persistence of the distal portion, which results in an aberrant retroesophageal subclavian artery.

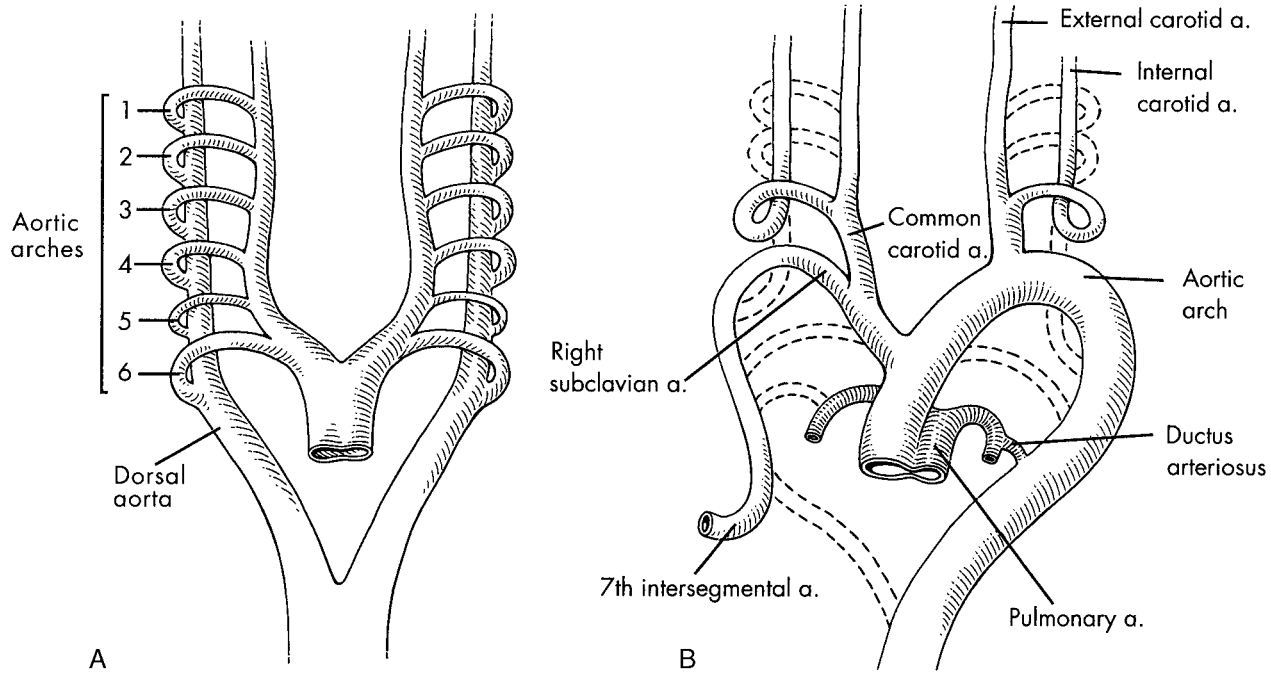

FIGURE 29-5 Development of the great vessels. **A**, Diagram of the paired dorsal and ventral aortas, which are connected by six pairs of aortic arches. Each of the six paired aortic arches is the arterial component of a branchial arch. **B**, Diagram at a later stage of development shows that the first, second, and fifth arches have disappeared (*broken lines*). Errors in the obliterative process result in vascular rings. (From Langman's Medical Embryology, 7th ed. Baltimore: Williams & Wilkins, 1995;214.)

SECTION TWO

CLINICAL EVALUATION

Assessment of airway problems in pediatric patients begins with a comprehensive history and physical examination. Information should be elicited about congenital, inflammatory, traumatic, or other conditions that may adversely affect the airway. The history should also include a review of any prior anesthetic records, as an increased risk of airway abnormalities may result from prior surgery, intubation, or radiation treatment to the face or neck.

The airways in infants and children are small, and slight narrowing produces signs of respiratory obstruction.[5] Pertinent signs or symptoms include snoring, apnea, daytime somnolence, stridor, and a hoarse voice. Respiratory obstruction is indicated by flaring of the nasal alae, retractions of the neck, intercostal muscles, and abdominal muscles, restlessness, and cyanosis.[5] On physical examination the presence of craniofacial or spinal malformation, obesity, abnormalities of dentition, enlargement of the tongue, and neck or facial masses should be noted.

STRIDOR

Stridor, which is defined as noisy breathing, is the audible result of turbulent airflow. Stridor may be either acute or chronic and may result from obstruction anywhere in the airway from the nasal cavity to the distal bronchi. Acute stridor is commonly caused by acquired conditions such as infection, trauma, or a foreign body.[6] The most common causes of chronic stridor in the infant are congenital laryngeal or tracheal anomalies such as laryngomalacia or tracheomalacia and vocal cord paralysis. Stridor may be associated with respiratory distress, the degree of distress dictating the urgency of the situation and the need for immediate clinical intervention. Significant respiratory compromise is an indication for endoscopy or intubation. In infants and young children, conventional emergency airway techniques, such as cricothyrotomy and transtracheal jet ventilation, are problematic because of limited surface landmarks and the relatively small larynx and trachea. Therefore, direct cannulation of the trachea by rigid bronchoscopy or emergent tracheotomy should be considered early in the management of the emergency airway in pediatric patients.[7]

The phase of respiration in which stridor occurs is the most important characteristic for localizing the site of airway obstruction. Stridor during inspiration usually indicates obstruction at or above the glottis. Biphasic stridor suggests subglottic or high tracheal obstruction, and expiratory stridor is characteristic of lower tracheal or bronchial obstruction.[6] Low-pitched stridor indicates nasal or oropharyngeal obstruction. High-pitched sounds usually indicate laryngeal obstruction.

There are other clinical characteristics that may suggest the etiology of the stridor. If stridor has been present since birth, then the most likely causes are congenital laryngomalacia, subglottic stenosis, vocal cord paralysis, or a vascular ring.[8] Laryngomalacia causes stridor that is more pronounced in the supine position and diminishes if the child is resting and in the prone position. Patients with significant vascular compression of the airway present with symptoms such as stridor, cough, recurrent lower respiratory tract infections, difficulty feeding, and reflex apnea.[9] Bilateral vocal cord paralysis is most often seen in children with neurologic abnormalities. Fever or cough suggests croup, and drooling or odynophagia is often a sign of epiglottitis. A history of prematurity and prior intubation in a child with stridor suggests the possibility of acquired subglottic stenosis. The relationship of stridor to feeding and the possibility of reflux and/or aspiration may indicate the need for gastrointestinal evaluation.[5]

Depending on the clinical situation and the severity of stridor, plain films may be obtained. However, if the diagnosis is uncertain or if immediate intervention is required, endoscopy should be performed. Flexible fiberoptic laryngoscopy has become the technique of choice to evaluate the pediatric larynx, especially when airway dynamics are of concern. Rigid direct laryngoscopy remains the preferred technique when laryngeal/tracheal surgery is planned or establishment and protection of the airway with intubation or bronchoscopy is required.[10] Manipulations such as extraction of foreign bodies can be performed only through the rigid endoscope. Endoscopy is more sensitive than radiographic examination in detecting airway lesions caused by laryngomalacia, subglottic stenosis, and tracheal stenosis, but the two methods are comparable for evaluating other common pediatric airway lesions.[11]

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea (OSA) in children results from airway obstruction and cessation of airflow for a finite period of time during sleep. Snoring, laborious breathing, and profuse sweating characterize OSA. When awake, children may have breath-holding spells and, during feeding, difficulty with breathing and coordinating swallowing. Daytime symptoms also include excessive sleepiness, with poor performance and behavior problems. Severe forms may be associated with failure to thrive or death.[12]

The most common cause of OSA in children is adenotonsillar hypertrophy, which is treated by tonsillectomy and adenoidectomy.[13] Less common causes of OSA in children include neuromuscular disorders, macroglossia, nasopharyngeal masses, craniofacial syndromes, obesity, and pharyngeal flaps following cleft palate repair.[13] OSA is also a feature of some genetic syndromes such as Down syndrome and Prader-Willi syndrome (short stature, obesity, and gonadal hypodevelopment). In many of these children OSA is multifactorial, and obstruction of the airway can potentially occur at multiple sites from fixed anatomic abnormalities as well as dynamic changes such as posterior displacement of the tongue during sleep (glossop-

Copyright © 2003, Mosby, Inc. All rights reserved.

tosis) and hypotonia of the hypopharyngeal and glossal musculature.[14]

The diagnosis of OSA is usually established by the clinical history alone. Most parents can vividly describe loud snoring, obstructive pauses, retractions, and mouth breathing. When the diagnosis is uncertain, studies such as polysomnography (sleep studies), sleep sonography, physical examination, and radiographs may confirm the diagnosis of OSA. Lateral plain films are useful for evaluating the size of the adenoids and tonsils and for excluding the presence of other obstructing lesions. If the diagnosis remains uncertain after the physical examination and plain films, airway fluoroscopy may determine the actual site of obstruction during quiet respiration or sleep.[15] Dynamic sleep fluoroscopy has been advocated as an adjunct to endoscopy in the identification and management of pediatric upper airway obstruction when hypopharyngeal collapse or multiple levels of obstruction are suspected.[16] This technique requires the administration of sedation to induce sleep followed by periodic lateral fluoroscopy in order to correlate anatomic changes in the airway with episodes of oxygen desaturation. Using dynamic sleep fluoroscopy, glossoptosis has been identified in 25% of pediatric patients referred for fluoroscopic sleep studies.[14]

Helical CT or CT with the capacity to scan during several respiratory cycles is also useful in diagnosing the site of obstruction in children with a questionable diagnosis of OSA. Multidetector CT with inspiratory-expiratory imaging may also be useful in the evaluation of patients with dynamic airway collapse.[17]

Ultrafast MR imaging is useful for localizing the sites of pharyngeal airway obstruction in patients with OSA. Multiple images are obtained using ultrafast pulse sequences at different anatomic levels.

SECTION THREE

RADIOGRAPHIC TECHNIQUES

PLAIN FILMS

When investigating a possible upper airway obstruction, the imaging modality of choice depends on the suspected location of the lesion and whether the airway compromise is acute or chronic. Impending or progressive airway obstruction necessitates rapid, efficient workup, often including same-day operative endoscopy. Commonly, the first examinations obtained are plain soft-tissue film radiographs of the sinuses, neck, and chest. Tightly coned, high-kilovoltage (to optimize soft-tissue detail and thus maintain resolution of the airway), magnified views of the airway are obtained in the lateral projection, and frontal airway films should be obtained when the symptoms are not emergent or life-threatening. The radiographic appearance of the pediatric airway is affected by patient position, crying, swallowing, and the phase of respiration. The lateral film should be obtained with the child upright when possible, with the neck in a neutral position or slightly extended, during deep inspiration. If the neck is flexed or the film is obtained during expiration or crying, the retropharyngeal soft tissues may appear abnormally prominent, simulating retropharyngeal pathology (Fig. 29-6). Sometimes the impression of a neck or mediastinal mass is created by the normal buckling of the trachea to the right on the anteroposterior (AP) examination.

When life-threatening airway obstruction is suspected, as in acute epiglottitis, some clinicians believe that a plain film is not initially needed because the time spent obtaining it

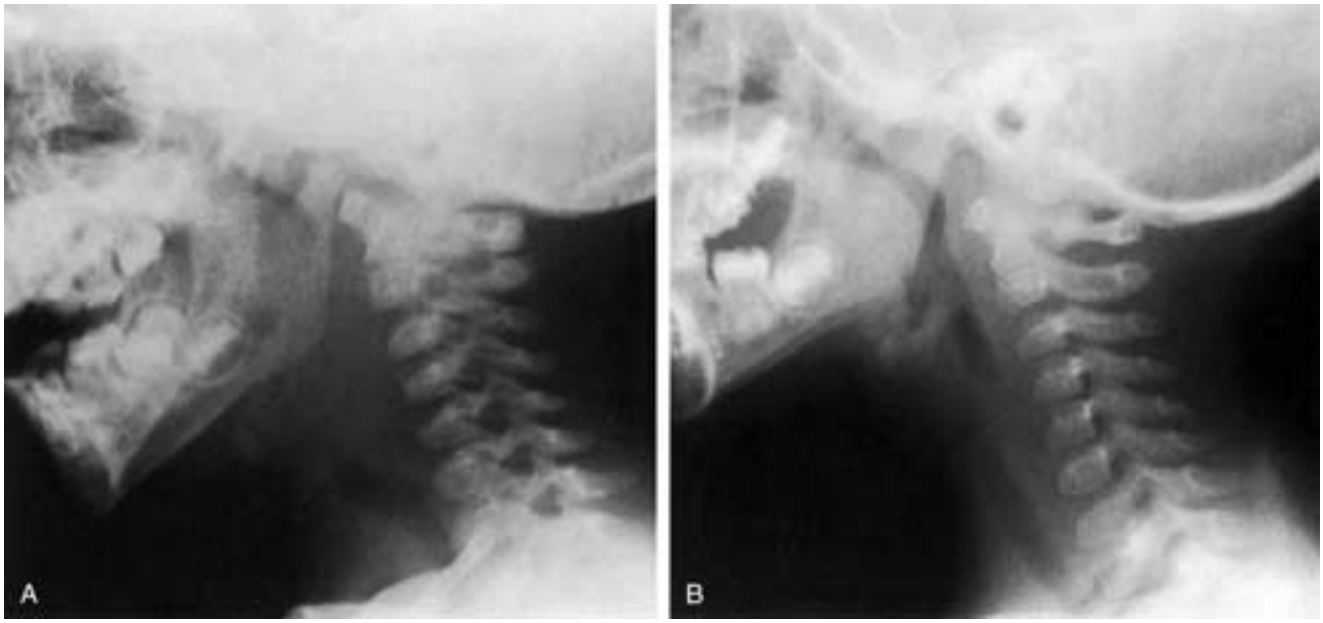

FIGURE 29-6 Importance of radiographic technique. Child with fever and drooling. **A**, Lateral plain film of the neck obtained while the child is swallowing shows retropharyngeal soft-tissue thickening simulating an abscess or a mass in the retropharynx. **B**, Repeat film 5 minutes later while the child is quiet shows normal retropharyngeal soft tissues. VIEW IMAGE

FIGURE 29-7 Normal lateral and AP radiographs in a 2-month-old infant. **A**, Lateral film obtained during inspiration, with the neck in the neutral position. Normal soft-tissue structures include adenoidal tissue (*A*), the free edge of the epiglottis (*thick white arrow*), aryepiglottic fold (*white arrowhead*), soft palate (*P*), tongue base (*T*), and calcified hyoid bone (*H*). Air-filled structures include the vallecula (*V*), laryngeal ventricle (*short white arrow*), subglottic airway (*white arrow*), and trachea (*long white arrow*). **B**, Normal AP radiograph shows air-filled pyriform sinuses (*short arrows*), true vocal cord (*long arrow*), subglottic airway (*s*), and trachea (*T*).

delays initiation of treatment. However, if a film is to be obtained, a single lateral film of the airway is usually all that is necessary to confirm the diagnosis. Additional frontal views only delay the workup and treatment and typically contribute little new information. A clinician should accompany the child to the radiology suite, and the radiologist should supervise the appropriate examinations, remaining in the department until the radiographic portion of the workup is completed. The child with acute airway obstruction should not be placed in the supine position or immobilized because these manuevers may exacerbate airway compromise.

Normal air-filled structures seen on the lateral plain film are the nasopharyngeal, oropharyngeal, hypopharyngeal, and supraglottic airways, as well as the valleculae, laryngeal ventricle, and infraglottic trachea (Fig. 29-7). Soft-tissue structures routinely visualized on the lateral examination are the palate, base of the tongue, adenoids, epiglottis, aryepiglottic folds, and retropharyngeal and prevertebral soft tissues (Fig. 29-7). The AP film displays the laryngeal and tracheal airway. Specifically, the false and true vocal cords, the laryngeal ventricles, the subglottic region, and the trachea can be identified.

On plain films, standard measurements for normal soft-tissue structures have been determined, and soft tissues exceeding the normal values may indicate an airway lesion. However, all measurements should be used with caution because tremendous variability is seen in the normal pediatric airway, especially with dynamic structures such as the epiglottis, pharyngeal soft tissues, and trachea. The retropharyngeal and prevertebral soft-tissue thickness is one of the most commonly measured regions, and the most frequently used measurement is the distance between the posterior pharyngeal air column and the anterior portion of the third or fourth cervical vertebral body. Normally in children, on a properly positioned film this distance should not exceed one half to three fourths the diameter of the vertebral body.[18]

Chest radiographs often are obtained when evaluating the child with airway obstruction. The entire trachea to the level of the bifurcation should be evaluated with respect to diameter, position, and patency.

FLUOROSCOPY

Fluoroscopy of the airway provides dynamic information not available with plain films. Video fluoroscopy with 105 mm spot films or digital images obtained at a rate of three to four frames per second allows fast imaging and is useful for evaluating the child with chronic airway obstruction. Changes in airway caliber during inspiration and expiration can be assessed over several respiratory cycles. The tracheal diameter increases during inspiration and decreases during expiration, and any paradoxical changes can be appreciated with dynamic fluoroscopy.[19] Dynamic examination of vocal

Copyright © 2003, Mosby, Inc. All rights reserved.

cord movement during quiet breathing and phonation (crying in the infant) can also be performed using fluoroscopy. The cords should abduct symmetrically during inspiration and adduct with phonation. On such a study, an unsuspected vocal cord paralysis can be diagnosed. However, fluoroscopy is limited by its inability to image the soft-tissue structures surrounding the airway. For example, narrowing of the tracheal airway by a neck mass can be seen, but the characteristics of the mass are determined better on cross-sectional imaging.

Barium esophagography, performed under fluoroscopic control, is often part of the workup of the pediatric patient with an airway problem, and this study is usually performed in conjunction with airway fluoroscopy. Lesions that may be detected on barium swallow studies include esophageal foreign bodies, congenital vascular rings and slings, mediastinal masses, and bronchopulmonary foregut anomalies. Patient aspiration may also be detected.

COMPUTED TOMOGRAPHY

CT adds important information about the soft tissues surrounding the airway. However, children often require sedation for these studies, and sedation routinely results in a decrease of the AP diameter of the pharynx at the level of the palatine tonsils and soft palate and at the level of the epiglottis.[20] When general anesthesia is used, there is distortion of the airway as a result of the endotracheal tube.

Lesions within the airway or involving the function of the airway, such as subglottic stenosis or tracheomalacia, are often best evaluated by fluoroscopy or endoscopy. Conversely, extraluminal disease is best studied with CT or MR imaging. Because the region of interest is limited, scans should be obtained using axial thin-slice collimation, usually 3 mm contiguous or helical images. Direct coronal MR imaging or direct or reformatted coronal CT is recommended for lesions of the skull base and nasopharynx, as well as those of the larynx and trachea, for assessment of the craniocaudal extent of disease. When a focal mass or an inflammatory lesion is suspected, intravenous nonionic iodinated CT contrast should be used.

Older children who cooperate can be scanned with conventional CT using a breath-hold technique. This helps ensure that the serial scans are performed during the same phase of respiration with similar lung volumes, thus decreasing the potential for respiratory misregistration artifacts. In younger or sedated children who cannot voluntarily suspend respiration, scanning is performed during quiet respiration. Early experience with airway measurements on cine or ultrafast CT suggested that cross-sectional airway areas were reduced in patients with obstructive sleep apnea and tracheomalacia, and that dynamic CT could show changes in these areas during different phases of the respiratory cycle.[21–23] However, the cine CT technique is not widely available clinically, and most radiologists have little or no experience with this technique.

Current spiral and multidetector CT technology, allowing volume scanning at a rapid speed, is now widely available. In older children, this technique allows the neck to be scanned during a single breath-hold. In infants, the entire airway can be scanned during a single 10 to 15 second or shorter acquisition period, often obviating the need for sedation. Sections that are 1 mm thin can be obtained routinely with the spiral technique, and these thin sections are necessary when evaluating a newborn or infant with a suspected small subglottic web, cyst, stenosis, hemangioma, or papilloma. To further aid the clinician, the region of narrowing should be described with reference to its distance from a fixed anatomic landmark such as the glottis, inferior cricoid, or carina. Dynamic imaging can also be performed, if necessary, through a specific level of airway obstruction. In this way, using static and dynamic airway imaging, lesions that change diameter with the respiratory cycle may be studied, complementing airway fluoroscopy. However, especially in pediatric patients, it is important to take the radiation dose into consideration when using these techniques. This limits the utilization of dynamic CT scanning.

MAGNETIC RESONANCE IMAGING

Most children under the age of 5 years require some form of sedation in order to undergo MR imaging. Where compromise of the airway is suspected, an anesthesiology consultation should be obtained, as a general anesthetic may be indicated to avoid the risk of sedating a child with a tenuous airway. The choice of coil and pulse sequence for MR imaging of the pediatric neck and airway will depend on the clinical indication for the examination. Surface coils may be of use if the region of interest is superficial and small (e.g., subglottic hemangioma). Multiplanar imaging should be acquired with T1-weighted, T2-weighted, and fat-suppressed, T2-weighted or fast spin-echo inversion recovery (FSEIR) imaging. Cardiac gating and respiratory compensation are useful if the airway lesion is in the thoracic trachea. Coronal T1-weighted images are especially useful to display a paratracheal mass that is causing extrinsic tracheal compression. Narrowing in any region of the airway should be confirmed with a second acquisition in an orthogonal plane. A sequence sensitive to flow-related enhancement (e.g., spoiled gradient recalled acquisition) is useful in evaluating suspected vascular anomalies. When imaging neck masses, gadolinium should be used with fat-suppressed, T1-weighted images.

SECTION FOUR

NORMAL ANATOMY

NASAL CAVITY

Because neonates are obligate nasal breathers, the nasal cavity is an important component of the pediatric airway. The air-filled nasal cavity extends from the nostrils to the posterior choanae. The lateral nasal walls should be straight or slightly concave medially (Fig. 29-8). The nasal septum consists of the vomer, the perpendicular plate of the ethmoid, and cartilage. The normal nasal septum is midline,

VIEW IMAGE

FIGURE 29-8 Normal nasal cavity in a 13-year-old child. Axial CT scan of a normal nasal cavity in a child is similar in appearance to that in an adult, with the nasal septum wider at its anterior portion, slightly concave lateral nasal walls, and a patent posterior choanae.

thicker anteriorly, and is separated from the turbinates by air. The anterior thickening is diamond-shaped and should not be mistaken for a mass. The mean width of the posterior choanal airspace in the newborn is 0.67 cm, increasing to 0.86 cm at 6 years and to 1.13 cm by 16 years of age.[24] In children less than 8 years of age, the vomer generally measures less than 0.23 cm in width and should not exceed 0.34 cm. In those over 8 years of age, the mean vomer width should not exceed 0.55 cm.[24]

NASOPHARYNX AND OROPHARYNX

The plane of the hard palate separates the nasopharynx from the oropharynx. On CT and MR imaging, the marrow within the bony hard palate is usually clearly identified. By comparison, the soft palate is primarily muscular. The junction between the soft and hard palates is well seen on CT and MR imaging (Fig. 29-9). The soft palate in the infant and child is a prominent structure on plain radiographs, separating the nasopharyngeal airway from the oropharyngeal airway. During quiet breathing the soft palate moves down, opposing the tongue base. However, during swallowing and phonation, the soft palate elevates and moves posteriorly, closing the nasopharynx and opening the oropharynx, which prevents nasal regurgitation.

The nasopharynx and oropharynx of the child differ from those of the adult in that they are smaller and normally have more lymphoid tissue within the mucosa and extending into the airway. The vertical height and depth of the nasopharynx increase during childhood, but the width, or distance between the eustachian tubes, does not significantly increase.[25] The primary lymphoid tissue of Waldeyer's ring consists of the adenoids (pharyngeal tonsils), the palatine (faucial) tonsils, and the lingual tonsils. The adenoids are situated in the posterior nasopharyngeal roof and upper posterior wall. On plain films and fluoroscopy they appear confluent with the prevertebral soft tissues, and are separated from the upper surface of the soft palate by the nasopharyngeal airway (Fig. 29-7A). The adenoids are not routinely seen at birth but are 1 to 5 mm thick in the normal 3-month-old. If no adenoidal soft tissue is seen by 6 months of age, hypogammaglobulinemia or an immune deficiency syndrome should be suspected. The adenoids normally begin to regress in adolescence, and in most people they have completely involuted by middle age. However, occasionally the adenoids can be identified in the fifth and sixth decades of life.

On CT, adenoidal tissue fills the posterior nasopharynx, is isodense to muscle on noncontrast CT, and enhances with iodinated contrast. A thin line of enhancement, probably indicating the submucosal veins, is usually seen between the adenoids and the nasopharyngeal wall (Fig. 29-10). Ventrally the adenoidal tissue is usually flat, but it can appear asymmetrically lobular or thickened. Occasional small calcifications, due to concretions in small lymphoid clefts, can be seen within the adenoids on CT. On T1-weighted MR images, the adenoids are isointense to slightly hyperintense with respect to muscle and are of lower signal intensity than fat. On T2-weighted images they are homogeneously hyperintense with respect to muscle (Fig. 29-11). Sometimes, focal round or oval foci of signal abnormality within the adenoids are seen on MR imaging. These probably represent small mucous retention cysts. The adenoidal tissue enhances slightly with gadolinium contrast agents (Fig. 29-11C).

The paired palatine tonsils can be identified radiographically by about 1 year of age, are greatest in size at about 4 years of age, and begin to involute after the age of 10 years.[26] The palatine tonsils may normally be obscured by the tongue base and mandibular angle on a lateral plain film. However, if the airway is distended (as occurs when the

FIGURE 29-10 Normal adenoids on CT in a 14-month-old child. **A**, Axial noncontrast CT shows adenoidal tissue, nearly isodense to prevertebral muscles, filling the nasopharynx. **B**, Same child scanned following intravenous iodinated contrast administration using a spiral technique. The adenoidal tissue enhances, but prevertebral muscles (*m*) do not. Notice the thin linear enhancement at the interface between the adenoids and muscle (*black arrows*). The adenoidal tissue characteristically fills the lateral pharyngeal recesses (*R*), is flat ventrally, and does not extend into the deep pharyngeal spaces. (Courtesy of Dr. John J. Alarcon, Scottish Rite Children's Medical Center, Atlanta, Georgia.)

child cries) or if there is significant tonsillar hypertrophy, these tonsils can be identified on a lateral plain film (Fig. 29-12). The lingual tonsils are located at the base of the tongue, usually just above the valleculae. The CT density and MR signal intensity of lingual and palatine lymphatic tissue is similar to those of the adenoids (Figs. 29-13 and 29-14).

The median and lateral retropharyngeal lymph nodes provide lymphatic drainage for the sinonasal cavities and pharynx. These nodes are seen on MR imaging in most infants and children (Figs. 29-14 and 29-15). Because they are isodense to muscle on CT, they are appreciated only when enlarged or necrotic. However, because of the numerous normal childhood infections, the efferent lymph vessels to these nodes usually become obstructed by the second decade of life, and these nodes are not commonly seen in the normal adult.

HYPOPHARYNX

The hypopharynx lies between the tip of the epiglottis and the cricopharyngeus, extending posterior to the larynx from the level of the hyoid bone to the lower cricoid bone. The middle and inferior constrictor muscles support the posterior and lateral walls of the hypopharynx. The anterior wall is bordered by the laryngeal cartilages and laryngeal inlet and anterolaterally by the aryepiglottic folds. The hypopharynx has two recesses, known as the pyriform sinuses, that are bounded medially by the lateral surfaces of the aryepiglottic folds and laterally by the thyroid cartilages and thyrohyoid membrane. At the inferior extent of the pharynx, the oblique fibers of the inferior constrictor end and the horizontal fibers of the cricopharyngeus muscle begin.[27] Between the lower edge of the oblique fibers and the upper edge of the horizonal fibers is Killian's dehiscence, the site of formation of Zenker's diverticulae. The cricopharyngealo muscle fibers serve as a pharyngoesophageal sphincter, remaining closed apart from deglutition, severe gastroesophageal reflux, and vomiting.

LARYNX AND TRACHEA

The pediatric larynx and trachea differ in appearance from their adult counterparts. Compared with the larynx of an adult, the pediatric larynx is smaller relative to the overall body size. Thin contiguous sections, no greater than 3 mm, are required to adequately image the pediatric larynx. The small size of the pediatric laryngeal airway explains why, with only minimal mucosal edema or swelling such as occurs with laryngotracheobronchitis, symptoms such as stridor and respiratory distress may occur. The newborn glottis is only 7 mm in the anteroposterior dimension. The newborn subglottis, the smallest area of the pediatric airway, measures only 4 to 5 mm in diameter.[28]

The larynx rapidly increases in size during the first 6 years of life and then gradually slows its growth until adolescence, when it reaches adult proportions. In the adult, only the male thyroid cartilage continues to change shape and grow on its external anterior aspect.[29] The change in voice character normally noted during puberty is secondary to growth of the vocal cords, histologic changes in the vocal folds (as the fibers change in density), and a change in the

Copyright © 2003, Mosby, Inc. All rights reserved.

angle of the thyroid cartilage.[29] Of these, the most important change appears to be the thyroid cartilage angle, which until puberty is 100° to 120° open posteriorly. The angle of the thyroid laminae decreases to approximately 90° in both sexes as the anteroposterior length of the glottis increases, but the male thyroid eminence becomes much more prominent.[28]

The pediatric larynx also changes significantly in shape during early life. In adults the glottis is the narrowest portion of the airway. However, in the infant the larynx has a characteristic funnel shape, which results in the subglottic region being the narrowest portion of the larynx and upper airway, as described earlier in this chapter. Below the subglottis, the pediatric airway again widens to a fairly uniform diameter that is maintained down to the level of the carina.

When viewed from above, the epiglottis is omega-shaped and is more angular in the infant than in the adult. This contour may be exaggerated in infants who have congenital laryngeal stridor. This characteristic shape and the resultant stridor disappear in most cases by the second year of life.[30] The glottic airway is elliptical in shape, with the greatest diameter in the anteroposterior dimension, the subglottis is round, and the trachea is ovoid and slightly flattened posteriorly (Fig. 29-16C–E). The tracheal shape is consistent between girls and boys.[31]

During the first several years of life, the pediatric larynx changes its position in the neck. Thus, the normal radiographic landmarks are different from those in the adult. The superior free edge of the epiglottis in the neonate is found at or near the C1 level, and the cricoid cartilage, representing the most caudal portion of the larynx, is at the C4-C5 level. The epiglottis can be visualized in the oral cavity in most infants, and because of the early rostral position of the larynx, the infant is an obligate nasal breather. By adolescence the epiglottis is found at the C2-C3

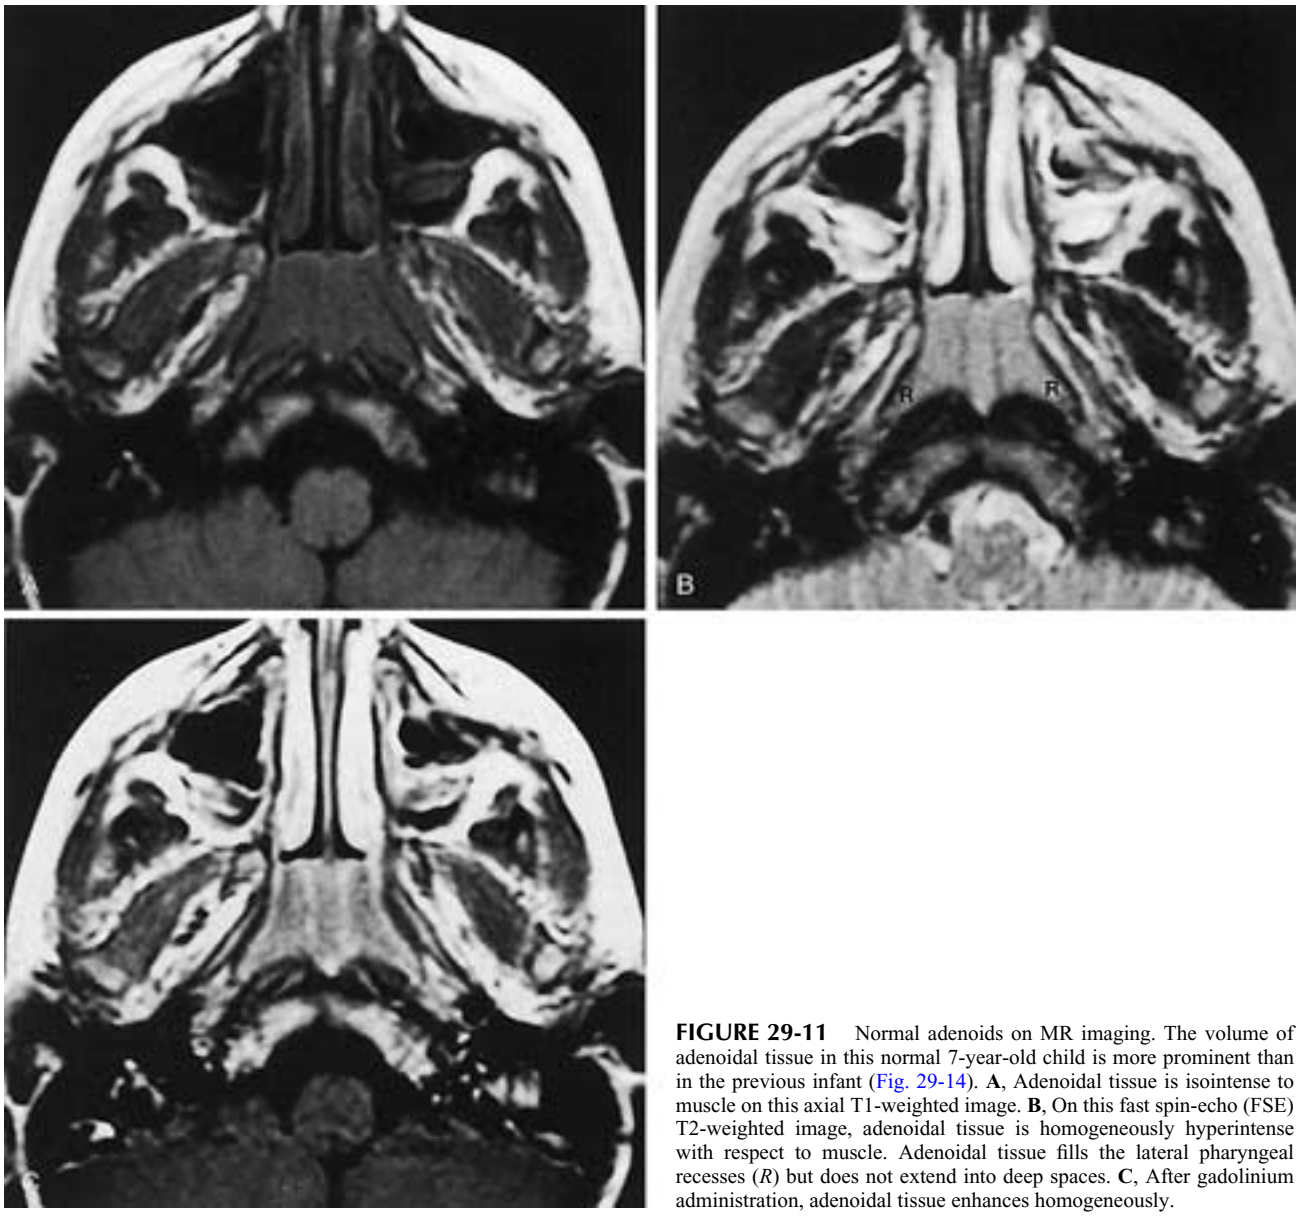

FIGURE 29-11 Normal adenoids on MR imaging. The volume of adenoidal tissue in this normal 7-year-old child is more prominent than in the previous infant (Fig. 29-14). **A**, Adenoidal tissue is isointense to muscle on this axial T1-weighted image. **B**, On this fast spin-echo (FSE) T2-weighted image, adenoidal tissue is homogeneously hyperintense with respect to muscle. Adenoidal tissue fills the lateral pharyngeal recesses (*R*) but does not extend into deep spaces. **C**, After gadolinium administration, adenoidal tissue enhances homogeneously.

level, and the cricoid is at the C6 level. The adult epiglottis is usually seen at the C3 level, with the cricoid at the C6-C7 level. The arytenoid cartilage, a radiologic landmark that helps localize the true vocal cord, is found at the C4-C5 level in children.

Although the cartilaginous framework for the larynx is established in the infant, the structures are not calcified at birth. The larynx is softer and the ligaments have greater laxity than they do in the adult larynx. The hyoid bone is the first laryngeal structure to ossify. Ossification of the hyoid bone is seen after 30 weeks' gestation. The body of the hyoid is ossified in infants older than 4 months, and the greater cornua is ossified in those older than 6 months. Ossification of the lesser cornua does not appear in children less than 15 years of age.[32] Premature calcification of the laryngeal cartilages in infancy is abnormal and may be associated with stridor.[33]

The cricoid cartilage is a complete cartilaginous ring, and it is the narrowest portion of the infantile larynx (Fig. 29-17). The anterior and lateral portions of the cricoid cartilage arch are narrow, and the posterior portion forms a thick lamina. The cricothyroid articulation is on the superolateral portion of the cricoid arch. This small depression articulates with the inferior horn of the thyroid cartilage. The cricothyroid ligament spans the gap between the cricoid and thyroid cartilages anteriorly.

The paired arytenoid cartilages sit on the superior rounded surface of the posterior lamina of the cricoid cartilage (Fig. 29-17B). The vocal ligament is attached to the anterior vocal process of the arytenoid cartilage, which is at the level of the cricoarytenoid joint.

The CT appearance of the pediatric larynx reflects the anatomic characteristics discussed. Children under the age of about 7 years may require sedation, so scans are obtained during quiet respiration, without breath-hold maneuvers. Therefore, respiratory motion artifact is common. The hyoid bone and the free edge of the epiglottis are seen at a higher level than in the adult, usually at the C1-C2 level or just at

space is fat density and only several millimeters thick, and the paraglottic fat is not as prominent as it is in the adult larynx. The aryepiglottic folds are thin, and the pyriform sinuses are usually air-filled. The thyroid cartilage is occasionally seen as a thin linear high-density structure, despite the fact that calcification is not seen on plain radiographs until the third decade (Fig. 29-16B,C). The ossified, or calcified, arytenoid cartilages, landmarks for the true vocal cords on CT of the adult larynx, are not seen in the pediatric larynx as discrete structures. Therefore, the level of the true vocal cords is determined primarily by the contour of the glottis, which has a characteristic oval shape (rather than the adult anteriorly narrowed, thin triangular shape). The glottis also can be localized by the location of the air-containing laryngeal ventricle. The ventricle is immediately cranial to the true cord, at the C3 level in the pediatric larynx, and can often be seen on lateral scout or plain films.[26] Most of the endolaryngeal structures, including the true vocal cords and intrinsic laryngeal muscles, are otherwise featureless on imaging (Figs. 29-16, 29-18, and 29-19). In the subglottis, a circumferential rim of soft tissue surrounds the airway. This is the noncalcified cricoid cartilage. The CT appearance of the pediatric larynx also differs from that of the adult because the cartilaginous structures, although fully formed, are not calcified, or ossified (Fig. 29-20).

High-resolution MR imaging of the pediatric larynx is difficult to perform because of the infant's relatively short, fat neck, the high position of the larynx, and respiratory artifact. On MR imaging there is little paraglottic fat. (Fig. 29-21). The nonossified cartilaginous laryngeal structures are hyperintense on T2-weighted images. On T1-weighted images, except for the thyroid cartilage, which is hyperintense to muscle, the cartilaginous structures of the larynx are isointense to soft tissue and are featureless. High-resolution MR imaging of the cadaveric larynx shows that the laryngeal cartilages are hyperintense to muscle on T2-weighted images, with a thin rim of low signal intensity around the cartilage (Fig. 29-21). However, such high-resolution imaging often is not clinically possible or necessary. As with CT, the airway contour indicates the airway level.

The cartilaginous trachea in children is uncalcified, smooth, and featureless on CT. Cartilaginous detail is, however, seen well on T2-weighted MR imaging. The tracheal contour is round anteriorly and flat posteriorly, at the membranous portion of the tracheal wall. Generally, the diameter of the normal infant trachea is slightly larger than that of the subglottis. The anteroposterior

dimension is slightly greater than the lateral dimension, except at the level of the innominate artery, where normal physiologic AP narrowing can occur. Absolute tracheal measurements on radiographs, fluoroscopic studies, CT, and MR imaging should be qualified with respect to phase of respiration because the trachea is a dynamic structure that changes shape and size during the respiratory cycle. The trachea is greatest in diameter during full inspiration and narrows slightly during expiration.[34] In normal infants the AP tracheal diameter may vary from 20% to 50% after breath-holding or crying.[34] In the newborn and infant, a tracheal diameter of 5 mm or more is considered normal. Normal tracheal measurements obtained on plain films or CT at maximal inspiration in children older than 10 years of age show coronal tracheal dimensions ranging from 0.9 to 1.8 cm and AP dimensions ranging from 1.1 to 1.8 cm.[35, 36] An abrupt change in tracheal diameter and configuration may be a more significant finding than any single measurement in the airway diameter.

SECTION FIVE

CONGENITAL AIRWAY DISEASES

NASAL OBSTRUCTION

Because the infant is an obligate nose breather, bilateral nasal airway disease often results in severe airway obstruction. Grunting, snorting, low-pitched stridor, and rhinorrhea are common presenting signs of nasal airway obstruction in the neonate or infant.[37] Although the most common cause of neonatal nasal airway obstruction is mucosal edema secondary to rhinitis, choanal atresia is the most common form of congenital nasal obstruction.[38, 39] Nasal airway obstruction may also result from turbinate hypertrophy, congenital syphilis (''snuffles''), pyriform aperture stenosis, and nasal cavity stenosis in association with craniofacial anomalies.[37, 38]

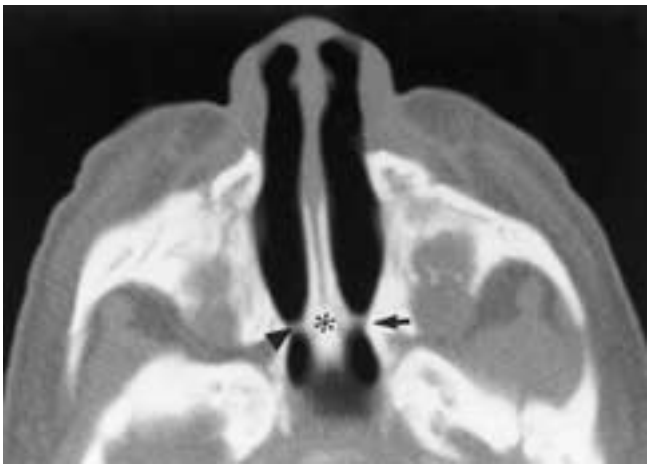

FIGURE 29-22 Bilateral membranous and bony choanal atresia in a 1-day-old girl. Axial CT scan obtained after suctioning the nasal cavity. There is thickening of the posterior vomer (*asterisk*). The posteromedial maxilla is bowed medially (*arrow*) and approximates the lateral margin of the vomer. There is a small membrane completing the atresia (*arrowhead*). Note the normal dimensions of the pyriform apertures anteriorly.

VIEW IMAGE

Choanal Atresia

Atresia of the posterior nasal cavity (choanae) is a developmental defect characterized by lack of communication between the nasal cavity and nasopharynx. This is the most common congenital abnormality of the nasal cavity, occurring in 1 of every 5000 to 10,000 live births.[38, 40] The anatomic classification of choanal atresia has been revised.[41] It was previously thought that choanal atresia was bony in 90% of cases and membranous in 10%.[42] However, with more accurate radiologic evaluation, it has been recognized that most if not all patients with choanal atresia have bony abnormalities. There is narrowing of the posterior nasal cavity with medial bowing and thickening of the lateral wall of the nasal cavity, with impingement at the level of the anterior aspect of the pterygoid plates and enlargement of the posterior portion of the vomer, with or without a central membranous connection (Fig. 29-22).[43] A combined bony and membranous malformation is found in approximately 70% of cases, and purely bony atresia occurs in about 30% of cases.[41] The existence of pure membranous atresia without a bony abnormality has been disputed.[41]

A number of theories have been proposed to explain choanal atresia: persistence of the buccopharyngeal membrane or of the bucconasal membrane, abnormal persistence or location of mesoderm-forming adhesions in the nasal choanal region, and misdirection of mesodermal flow.[40] The last mechanism links the development of choanal atresia to a mesodermal defect caused by faulty neural crest cell migration.[40, 44] Abnormal development, migration, or interaction of neural crest cells is thought to produce maldevelopment in the region of the nasal and palatal processes surrounding the nasobuccal membrane. The neural crest cell theory might help to explain the association of other craniofacial and distant malformations with choanal atresia.[44]

The clinical diagnosis of choanal atresia requires a high index of suspicion. Bilateral choanal atresia is a potentially life-threatening disorder that presents in the neonatal period. Symptoms range from intermittent mild to severe respiratory distress with cyanosis that is aggravated by feeding and alleviated by crying.[40, 45, 46] The diagnosis is suggested by an inability to pass nasal catheters or by absence of nasal mirror misting.[47] Bilateral choanal atresia should be promptly diagnosed and management initiated with insertion of an oral airway to alleviate symptoms.[45]

Approximately 75% of children with bilateral choanal atresia have other congenital abnormalities, as exemplified by the CHARGE association.[48, 49] The acronym CHARGE refers to a clustering of malformations that occurs more frequently together than expected on the basis of chance.[50, 51] These malformations include coloboma of the eye or microphthalmia (C), cardiovascular malformations (H), choanal atresia (A), developmental and growth delay (R), genital hypoplasia (G), typical external ear anomaly and/or hearing defects (E), and cranial nerve dysfunction.[52] The criteria for the diagnosis of CHARGE association have been recently revised.[52] Major criteria occur commonly in CHARGE association but are relatively rare in other conditions. These are coloboma, choanal atresia, characteristic ear abnormalities, and brainstem and cranial nerve dysfunction. Minor characteristics occur less commonly or are less specific for CHARGE. Heart defects, genital hypoplasia, orofacial clefting, tracheoesophageal fistula, short stature, and developmental delay are now considered minor criteria.[52, 53] The prevalence at birth of the CHARGE association is estimated at 1:100,000.[52] The diagnosis is firmly established when all four major criteria or three major and three minor criteria are present. The diagnosis also needs to be considered in any infant with one or two major and several minor characteristics.[52] The CHARGE complex is generally considered to be a sporadic condition. However, occasional familial cases, chromosomal abnormalities, and a significantly higher mean paternal age at conception have led some to consider an underlying genetic abnormality and to propose a subset of patients within the association who have a true syndrome.[54] Possible etiologies include defects of neural crest cells and the neural tube segment from which

these cells are derived, chromosomal deletion, and teratogenic exposure.[54, 55]

Although exact figures vary in the literature, about 50% to 60% of cases of choanal atresia are unilateral (Fig. 29-23).[41] Patients with unilateral choanal atresia usually present later in infancy or childhood with persistent unilateral nasal discharge or feeding problems. Although the presentation of unilateral choanal atresia is not as dramatic as bilateral choanal atresia, significant airway and/or feeding symptomatology may be present in a substantial number of children under 1 year of age.[56]

Radiologic evaluation of choanal atresia should be obtained after stabilization of the patient. CT is performed to identify the nature and severity of the anatomic deformity and to estimate the size of the nasopharynx. When the diagnosis is questionable, CT will differentiate other causes of bilateral nasal obstruction such as pyriform aperture stenosis or bilateral nasolacrimal duct cysts from choanal atresia (Fig. 29-24). Unilateral causes of nasal obstruction such as nasal foreign body, turbinate hypertrophy, septal deviation, antrochoanal polyp, or nasal tumor can also be differentiated from choanal atresia by CT.

The CT examinations are obtained with the patient supine. Agents can be suctioned and topical nasal vasoconstriction administered prior to commencing the scan to minimize accumulated nasal secretions in an effort to optimize assessment of any membranous component of atresia[24] (Fig. 29-22). Contiguous 1 to 1.5 mm scans of the nasopharynx should be obtained with the imaging plane parallel to the hard palate. Prospective high-resolution (edge enhancement) bone filters may be helpful because the skull base is only partially ossified at birth and conventional bone window settings may not permit adequate visualization of bone margins. Intravenous contrast is not required for the imaging of choanal atresia.

On CT scans the width of both posterior choanae at maximum stenosis and the maximum width of the inferoposterior vomer can be measured.[24] The major bony component of the atresia is an abnormal widening of the vomer (Fig. 29-22). Typically, the posteromedial maxilla is bowed medially and approximates or is fused with the lateral margin of the vomer. The mean width of the posterior choanal airspace in the newborn (measured from the lateral wall of the nasal cavity to the vomer) is 0.67 cm, increasing to 0.86 cm at 6 years and to 1.13 cm by 16 years of age.[24] In patients less than 8 years of age, the vomer generally measures less than 0.23 cm in width and should not exceed 0.34 cm; in children over 8 years, the mean vomer width is 0.28 cm and should not exceed 0.55 cm.[24] The thickness of the bony atretic plate should be reported because this may influence the surgical approach. In general, the thicker the plate, the more difficult the surgical repair.

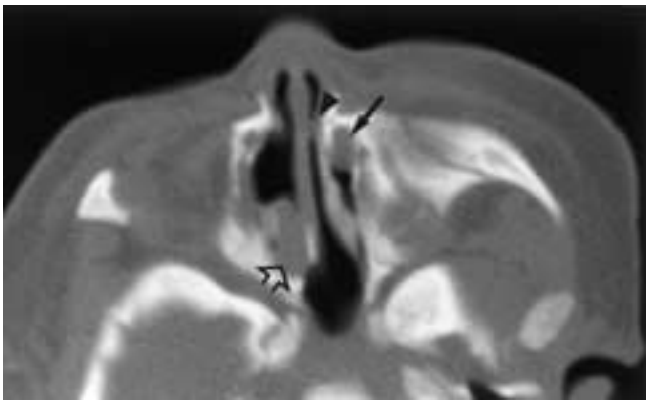

FIGURE 29-24 Nasal obstruction in a 2-day-old girl. Axial CT demonstrates unilateral choanal atresia (*open arrow*), pyriform aperture stenosis (*arrowhead*), and a nasolacrimal duct cyst (*black arrow*). Contrast these findings with those seen in Figure 29-22.

VIEW IMAGE

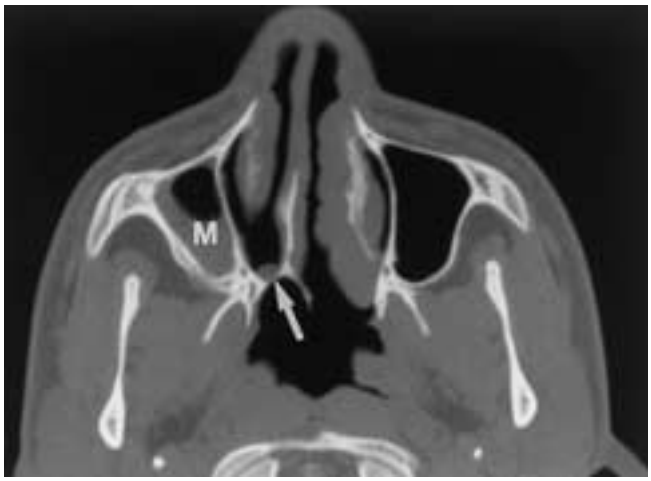

FIGURE 29-23 Unilateral choanal atresia in a 15-year-old boy. Axial CT demonstrates bony atresia of the right posterior choana. A thin wafer of bone (*arrow*) closes the space between the vomer and the posteromedial maxilla and pterygoid plates. There is hypoplasia of the right maxillary antrum (*M*), which contains mucoperiosteal thickening and secretions.

VIEW IMAGE

The membranous components of atresia are characterized by soft tissue filling the posterior choanae, associated with narrowing of the posterior choanae just anterior to the pterygoid plates (Fig. 29-22). The obstructing choanal membranes may be thin and strand-like or thick and plug-like. In patients with choanal abnormalities the nasal cavities may contain air, soft tissue, fluid secretions, or hypertrophied inferior turbinates. Topical vasoconstriction helps differentiate associated reversible changes from fixed obstructing lesions.

Surgical correction of bilateral choanal atresia is performed as soon as possible after the diagnosis has been made. The type of atresia and the thickness of the bony atresia plate, as determined by CT, determine the surgical approach. There has been little consensus regarding the optimal surgical approach to choanal atresia.[57] Transpalatal, transnasal, transseptal, and sublabial approaches have all been utilized, with varying results.[45, 57] Recently, the transnasal endoscopic drill-out procedure has emerged and been advocated as a safe and efficacious method with the best possibility of long-term nasal patency.[45, 57] This procedure usually entails the use of power instruments to perform mucosal incisions and bony resection of the atretic plate and vomer.[57] Puncture and curettage techniques without adequate resection of the vomer may lead to postoperative stenosis.[41] Multiple revisions are more likely to be required for small neonates and those with associated anomalies.[45] Postoperative nasal stenting is also frequently utilized.

Copyright © 2003, Mosby, Inc. All rights reserved.

Postsurgical persistent or recurrent choanal stenosis, usually caused by postoperative scar or an incompletely resected bony atretic plate, is also best evaluated with CT.[46] Laser resection can be considered for soft-tissue cicatrix.[41]

Nasolacrimal Duct Cysts

Most cases of nasolacrimal duct (NLD) cysts are thought to result from failure of canalization and partial or complete obstruction of the NLD. These cysts, which may be unilateral or bilateral, usually present in early neonatal life. The level of obstruction is usually at Hasner's valve, the most inferior point of the NLD, which is located beneath the inferior turbinate within the inferior meatus.[58] Retained secretions accumulate in the dilated NLD, with resultant cystic protrusion of the duct into the inferior meatus at the nasolacrimal ostium. In some cases, endoscopic contrast studies have demonstrated patency of the NLD in the presence of an NLD cyst. It has been suggested that these cases may be due to a diverticulum or duplication of the NLD.[58] Other etiologies of NLD obstruction typically present in older children and include tumors, granulomatous diseases such as sarcoid, tuberculosis, foreign body, and ectopic teeth. An increased incidence of NLD stenosis has also been noted in children with syndromic disorders such as trisomy 21 and branchio-oto-renal and branchi-oculo-facial syndromes.[59, 60]

Presenting signs of NLD cyst include a medial canthal mass due to dacryocystocele (dilatation of the lacrimal sac), epiphora, nasal obstruction, and respiratory distress. In the absence of a dacryocystocele, NLD cysts may be clinically indistinguishable from bilateral choanal atresia. Chronic inflammatory changes may be found in the walls of NLD cysts, suggesting the possibility of an intrauterine inflammation.[61] Bilateral NLD cysts present in early life with nasal obstruction. Unilateral mucoceles are uncommon.

CT evaluation should be performed using a technique similar to that described for choanal atresia. CT shows rounded, bilateral or unilateral, homogeneous soft-tissue density structures in the anterior and inferior nasal cavities (Figs. 29-24 to 29-26).[61] The inferior turbinates may be thinned and medially displaced. Unilateral cysts sometimes result in deviation of the nasal septum. NLD cysts may also occur in association with other abnormalities such as choanal atresia (Fig. 29-24).

Most cases of congenital NLD cysts resolve spontaneously within 12 months. For persistent NLD cysts, nasal endoscopy in conjunction with lacrimal probing is used to identify the precise site of opening of the NLD and the nature of obstruction. This technique minimizes the risk of creating a false passage, as may occur with blind lacrimal probing.[62]

Pyriform Aperture Stenosis

Congenital nasal pyriform aperture stenosis (PAS) is a rare anomaly characterized by narrowing of the anterior bony nasal apertures. The clinical presentation depends on the severity of the stenosis. Symptoms include respiratory distress immediately after birth, cyclical cyanosis relieved by crying, or difficulty breathing during feeding. It may be difficult or impossible to insert a nasogastric tube into the nose. Congenital PAS must be differentiated from other causes of nasal obstruction such as bilateral choanal atresia.

PAS may occur as an isolated anomaly or in association with dysmorphic features such as holoprosencephaly, hypopituitarism, a single central megaincisor, hypotelorism, cleft palate, and clinodactyly.[63, 64] Holoprosencephaly is a genetically and phenotypically heterogeneous disorder involving development of the forebrain and midface, with an incidence of 1:16,000 live born and 1:250 induced abortions.[65] Alobar holoprosencephaly, the most severe form, is associated with complete failure of division of the forebrain, as well as facial anomalies such as anophtalmia or cyclopia and a primitive nasal structure (proboscis) and/or midfacial clefting.[66] In milder forms, hypotelorism, single maxillary central incisor, and defects of the upper lip and/or nose characterize facial dysmorphism. Congenital PAS without a central megaincisor is generally an isolated anomaly with no intracranial defects.[63]

The etiology of PAS is unclear, but it may be related to bony overgrowth of nasal processes of the maxilla as part of

a developmental field defect or may be due to abnormal growth of the primary palate.[63, 67–69] Cytogenetic examination has revealed anomalies of chromosome 7, 13, or 18 in some cases.[64, 70] Defects in the cell signaling pathway involving the Sonic hedgehog gene, genes from other signaling pathways, defects in cholesterol biosynthesis, and teratogens have all been shown to cause holoprosencephaly in humans.[66, 71–73] Sonic hedgehog appears to have a role in coordinating the proliferation and survival of cells of the neural tube and cranial neural crest and is essential for morphogenesis of the frontonasal and maxillary processes, which give rise to the midface and upper face.[72, 73] Transient loss of sonic hedgehog signaling in the embryonic face inhibits growth of the primordia and results in defects analogous to hypotelorism and cleft lip/palate, characteristics of the mild forms of holoprosencephaly.[72]

CT of PAS should be performed as described for choanal atresia, but the scans should be extended through the maxillary alveolar ridge to evaluate for possible dental abnormalities. CT shows thickening of the nasal process of the maxilla, which results in narrowing of the anterior aperture, the narrowest portion of the nasal airway (Fig. 29-27). The adjacent anterior nasal septum may also be thinned. In addition to the pronounced narrowing of the anterior and inferior nasal apertures, the width of the nasal passage as a whole is generally also narrower than that of age-matched controls.[68] CT may also show a hypoplastic triangular hard palate with a marked midpalatal vomerine ridge and a median maxillary single central incisor tooth (megaincisor) (Fig. 29-27).[68, 69] Patients with a central megaincisor have an increased incidence of pituitary insufficiency and holoprosencephaly.[63] Therefore, MR imaging of the brain and pituitary is recommended in these patients. In addition to holoprosencephaly, MR imaging

may demonstrate absence of the anterior pituitary gland and infundibulum.

Initial management of PAS is aimed at establishing an airway. Subsequent treatment is determined by the overall prognosis of the infant and the symptomatic severity of the stenosis.

Other Forms of Nasal Stenosis and Nasal Agenesis

Stenosis within the nasal cavity can be the result of maxillary hypoplasia or turbinate hypertrophy. In children with syndromic craniosynostosis, midfacial retrusion is generally associated with narrowing of the entire nasal and nasopharyngeal passages as well as some reduction in choanal dimensions.[74] Although there have been reports of ''choanal atresia'' in Apert syndrome, it is generally the anterior third to midportion of the nasal cavity that is maximally narrowed in these children, and a diagnosis of choanal stenosis is not usually supported by CT.[69] Nasal stenosis has also been reported to be a feature of the Antley-Bixler syndrome. This uncommon syndrome was first named in 1975 and is characterized by multiple malformations of cartilage and bone including multisynostotic osteodysgenesis, midface hypoplasia, choanal atresia or stenosis, femoral bowing, neonatal fractures and multiple joint contractures and, occasionally, urogenital, gastrointestinal, or cardiac defects.[75–77]

Congenital absence of the nose with failure of formation of the nose, nares, and nasal cavities is rare. Associated anomalies include maxillary hypoplasia, a high-arched or cleft palate, low-set ears, and ocular anomalies (e.g. hypertelorism, micropthalmia, coloboma, and occluded or absent nasolacrimal ducts) (Fig. 29-28).[78, 79] Associated intracranial anomalies may include frontal encephalocele, absence of the olfactory bulbs and tracts, minor frontal gyral abnormalities, and agenesis of the corpus callosum. Theories of pathogenesis include failure of invagination of the nasal placodes, premature fusion of the medial nasal processes, lack of resorption of the nasal epithelial plugs, and faulty neural crest cell migration.[80]

Congenital absence of the nose has been detected with antenatal sonography.[79] Postnatal evaluation of these infants involves the use of both CT and MR imaging. CT with 1 to 3 mm increment helical images in the axial plane is used to provide bony anatomic detail for surgical planning (Fig. 29-28). Thin-section high-resolution multiplanar MR images are obtained to assess for the presence of associated malformations such as frontal cephalocele, and to document the dimensions of the space between the anterior cranial fossa and the hard palate.[79]

Nasopharyngeal Atresia

Nasopharyngeal atresia (NA) is an extremely rare malformation that results in complete isolation of the nasal cavity from the oropharynx.[81] Patients present early in life with severe respiratory obstruction. The diagnosis is made when a nasogastric tube cannot be passed more than 3 to 4 cm. The most important differential diagnosis is choanal atresia. CT of NA demonstrates absence of air in the posterior nasal cavity or nasopharynx. The posterior choanal passages end blindly, the posterior vomer is wide, and both the vomer and the hard palate are fused to the central skull base (Fig. 29-29). The soft palate is absent. Soft-tissue density material occupies the nasal cavities. Imaging on conventional CT may not clearly delineate the abnormality, and therefore sagittal reformatted images or sagittal T1-weighted MR imaging should be performed. This study shows absence of the uvula and nasopharynx, confirming the

diagnosis. This complex anomaly is managed by tracheotomy and subsequent reconstruction. Cleft lip has been associated with NA.[81]

Meningocele, Encephalocele, Nasal Dermoid, and Neuroglial Heterotopia

Nasal obstruction resulting from meningoceles, encephaloceles, nasal dermoid, or nasal neuroglial heterotopia is uncommon and results from errors in nasofrontal development.[82–86] The embryologic basis and general description of these anomalies are discussed in detail in Chapter 1.

CRANIOFACIAL MALFORMATIONS

Upper airway obstruction is frequently a feature of craniofacial syndromes and is often due to compromise of the airway at more than one anatomic location. Excluding isolated cleft palate anomaly, approximately 20% of children with major craniofacial bony anomalies require tracheotomy to alleviate airway compromise.[74] Early severe airway obstruction in these children is most often associated with an inadequate nasal airway, usually in the setting of additional oropharyngeal anomalies. Severe midface retrusion with nasal and nasopharyngeal stenosis may be mistaken for choanal atresia or stenosis. This has important therapeutic implications, as operative procedures to enlarge the posterior choanae are not helpful with these midface deformities.[74] Upper airway compromise may manifest clinically as nasal obstruction, laborious breathing, and obstructive sleep apnea, sometimes with cor pulmonale. Severe airway obstruction for which tracheotomy is required is most commonly associated with syndromic forms of craniosynostosis (e.g., Crouzon, Pfeiffer, or Apert syndrome), mandibulofacial dysostosis (Treacher Collins or Nager syndrome), and hemifacial microsomia.[74] Severe variants of Apert and Pfeiffer syndromes sometimes also have tracheal sleeve abnormalities that produce distal tracheal stenosis and/or lack of tracheal distensibility with sometimes fatal lower airway compromise from respiratory inefficiency, inability to clear secretions, and/or increased vulnerability to surface injury from tracheal suctioning.[74, 87] Interestingly, the presence of a cleft palate seems to provide additional nasal airway in patients with midface retrusion who may require long-term tracheotomy following cleft palate repair.[74]

Procedures used to alleviate airway obstruction include midface advancement, mandibular expansion, tonsillectomy and adenoidectomy, uvulopalatopharyngoplasty, anterior tongue reduction, and endoscopic tracheal granuloma excision. The choice of treatment depends on the nature and severity of airway obstruction. Infant tracheotomy, when indicated, can normalize body growth and development until such time as sufficient facial growth has occurred or definitive surgery such as midfacial advancement can safely be performed.[74] In some patients, obstructive sleep apnea may become evident only when the size of the lymphoid tissues of Waldeyer's ring is maximal. In these children, adenotonsillectomy alone may produce symptomatic improvement.

Of all the cleft syndromes, unilateral cleft lip and palate has the most severe reduction in nasal airway area.[88] Nasal septal deformities, septal spurs, turbinate hypertrophy, and

malpositioned teeth associated with cleft syndromes also result in nasal airway encroachment (Fig. 29-30). Although the nasal airways are accessible to direct clinical inspection, CT should be obtained before craniofacial surgery because size, asymmetry between sides, septal abnormalities such as lateral deviation or spurs, and turbinate anomalies or hypertrophy are details that should be conveyed to the surgeon.

Facial duplications are extremely rare and range from localized anomalies to complete doubling of all facial elements.[89] This anomaly is also known as *diprosopus*, referring to varying degrees of facial duplication with a single trunk and normal limbs.[90] Cleft lip and palate, macrostomia, multiple uvulae, hypertelorism, and intraoral or intranasal hamartomatous masses may accompany duplication of the maxilla, mandible, or both (Fig. 29-31).[89] Anomalies involving the brain, heart, kidneys, and spine have been described in children with facial duplications.[91, 92] It has been hypothesized that diprosopus results from duplicated neural crest cell derivatives following an initial duplication of the notochord.[92] The anomaly has also been linked to excessive Sonic hedgehog signaling.[72]

Helical CT with 3 mm increments in the axial plane with multiplanar 2D reformatted images and a three-dimensional (3D) model of the anomaly can be obtained to delineate the bony anatomy prior to reconstructive surgery (Fig. 29-31A). The skull base should be assessed for cephaloceles or defects, and the soft tissues of the nose, nasopharynx, and oropharynx should be assessed for hamartomatous masses (Fig. 29-31C). MR imaging provides useful ancillary evaluation for hamartomas, cephaloceles, and anomalies of the brain (Fig. 29-31D,E)

OROPHARYNGEAL OBSTRUCTION

Thyroglossal Duct Cyst and Ectopic Thyroid

The embryology of the thryoglossal duct is reviewed in Chapter 33. Of all the locations for thyroglossal duct cysts, those located at the base of tongue (foramen cecum) or vallecula are more likely to present with airway obstruction. CT or MR imaging is performed to characterize the mass, to define the extent of the cyst and its relationship to the larynx, and to exclude other lesions such as dermoid cyst, cervical adenopathy, hemangioma, lipoma, or lymphatic malformation. On CT, suprahyoid thyroglossal duct cysts are typically midline, rarely occurring more than 2 cm laterally (Fig. 29-32).[93] Simple thyroglossal duct cysts are low in density, with a thin rim that does not enhance significantly. If infected or if there is a history of infection, the cyst may have a higher density, with internal septations and rim enhancement.[94] On MR imaging, the cysts have either low or high signal on T1-weighted images and high signal on T2-weighted images. Rim enhancement is typical.

If a solid mass is seen in association with a presumed thyroglossal duct cyst, two entities should be considered: (1) ectopic thyroid tissue, which may occasionally be seen within the cyst wall or tract, or, rarely, (2) carcinoma, either papillary thyroid or squamous cell.[93, 95] If ectopic thyroid tissue coexists within a thyroglossal duct cyst and if this tissue is the patient's only functioning thyroid tissue, resection of the ectopic thyroid with the cyst will render the patient permanently hypothyroid.[96]

Malignancy, usually papillary adenocarcinoma, is a rare occurrence in a thyroglossal duct cyst. Most patients with thyroglossal duct cysts and associated malignancy are adults, but there are reports of carcinomas occurring in children as young as 6 years old.[97] Thyroid carcinoma arising in a thyroglossal duct cyst may be clinically indistinguishable from a benign thyroglossal duct cyst. However, carcinoma should be considered in thyroglossal duct cysts that have a mural nodule, calcification, or both (Fig. 29-33).[98]

The treatment of thyroglossal duct cysts is surgical excision using the Sistrunk procedure, in which the entire cyst, tract, and central body of the hyoid bone are resected en bloc.[99] Sistrunk's operative approach has been advocated to reduce the incidence of postoperative recurrence.[100]

Ectopic thyroid tissue at the base of the tongue, known as lingual thyroid, is the most common location for ectopic thyroid to occur, yet it is a rare cause of stridor in the infant.[101, 102] Of these patients, 70% have no other functioning thyroid tissue, and complete surgical resection may result in permanent hypothyroidism.[103] Congenital hypothyroidism and stridor suggest the diagnosis of lingual thyroid.[101] An ^{123}I scan, the diagnostic test of choice, shows uptake in the tongue base mass and can identify the presence of other thyroid tissue, usually in its normal location (Fig. 29-34). In most cases this is the only imaging test needed. If other imaging is required, ultrasound shows a solid mass, differentiating the ectopic thyroid from a thyroglossal duct cyst. CT without contrast shows a high-density mass at the tongue base. Iodinated contrast should not be used in this setting if it is anticipated that radionuclide imaging will be needed to confirm the diagnosis. On MR imaging, the lingual thyroid is hyperintense or isointense with respect to the intrinsic tongue muscles on both T1-weighted and T2-weighted images (Fig. 29-35). Regardless of the test performed, imaging should include the thyroid bed in an

attempt to identify thyroid tissue in its normal location. Airway obstruction mandates surgical excision. Otherwise, hormonal suppression with thyroid hormone is the treatment of choice.

Lingual Cysts

Various other cysts may occur in the lingual region, including mucous retention cysts, vallecular cysts, salivary retention cysts, dermoid cysts, and lingual cysts of developmental origin with either respiratory or gastric epithelium. Lingual cysts in infancy may be large enough to cause stridor and dyspnea, and occasionally result in sudden infant death.[104] A vallecular cyst, also known as a mucous retention cyst, often has to be differentiated from ectopic thyroid or a thyroglossal duct cyst on imaging studies (Fig. 29-36). The vallecular cyst may be similar in appearance to a thyroglossal duct cyst or dermoid cyst, but it is easily distinguished from a solid mass such as ectopic thyroid.

Dermoid cysts are uncommon benign developmental lesions that result from embryologic entrapment of ectodermal cells at lines of fusion in the embryo.[105] Oral cavity dermoids account for less than a quarter of head and neck dermoids and are usually located within the anterior floor of the mouth (Fig. 29-37). Most dermoids are seen in young adults; however, congenital sublingual dermoids occurring in infancy have been described.[106] Massive cysts may encroach upon the airway. Like thyroglossal duct cysts, dermoid cysts usually are midline, but they are not usually adherent to the hyoid bone. Like dermoid cysts elsewhere in the body, the lesion is usually sharply circumscribed and hypodense on CT (Fig. 29-38). On MR imaging, signal intensity ranges from intermediate to low on T1-weighted images and high on T2-weighted images (Fig. 29-37). Some signal heterogeneity may be observed. If focal regions of fat density (CT) or fat signal intensity (MR imaging) are seen within the cyst, the lesion is a dermoid.[107] Faint marginal enhancement may be seen. Dermoid cysts are treated by complete surgical resection of the cyst and any associated sinus tract or stalk. At surgery, the dermoid cyst may be

filled with a cheesy white material containing skin, skin appendages, hair, or desquamated epithelium.

Obstruction of a sublingual gland duct may lead to an enlarging floor of the mouth or tongue mass known as a ranula. Although ranulas are common, airway obstruction from these lesions is unusual. Imaging shows a cystic mass in the floor of the mouth or tongue.

Primitive foregut cysts of either respiratory or alimentary origin are uncommon congenital defects of the developing airway and gastrointestinal tract.[108] When the oral cavity is involved, the cyst is usually located in the tongue or floor of the mouth (Figs. 29-39 and 29-40).[109] These cysts are usually discovered during infancy but may not appear until well into adulthood. The cyst may present as a mass or with symptoms such as difficulties with feeding, swallowing, and respiration.[108, 109] Heterotopic gastrointestinal cysts of the oral cavity have an enteric lining and are thought to originate from entrapment of undifferentiated endoderm within the oral cavity during the third to fourth week of fetal life.[108, 109] The cyst may range in size from less than 1 cm to 9 cm, with most lesions being 1 to 3 cm in size. Cysts containing respiratory epithelium have also been reported (Figs. 29-39 and 29-40).[110, 111] This developmental anomaly is believed to originate from abnormal detachments of accessory lung buds from the ventral foregut.[111] The histologic and clinical

FIGURE 29-37 Dermoid cyst in a young child. **A**, Midline sagittal FSEIR image reveals that the sharply circumscribed cyst (*arrow*) is isointense with CSF. **B**, Contrast-enhanced, sagittal T1-weighted MR image reveals the hypointense, nonenhancing dermoid cyst (*arrow*) in the anterior floor of the mouth.

features and embryogenesis of both types of cysts overlap, and both respiratory and gastric epithelium may be present.[110] CT or MR imaging generally reveals a unilocular cyst with variable signal intensity, depending on the contents of the cyst (Fig. 29-39). Although usually hypointense on T1-weighted images, proteinaceous contents or blood products will produce T1 shortening (hyperintensity) (Fig. 29-40). The cyst contents are usually hyperintense on T2-weighted images. There is little if any marginal enhancement following the administration of gadolinium. The treatment of choice is complete surgical excision of the cyst.[111] However, aspiration of the cyst can be performed to improve access to the oropharynx for intubation prior to surgical resection.[112]

Macroglossia and Glossoptosis

Enlargement of the tongue with protrusion beyond the teeth or alveolar ridge in the resting position is termed *macroglossia*. Congenital macroglossia is associated with a variety of syndromes and conditions such as trisomy 21, Beckwith-Wiedemann syndrome, hypothyroidism, and the mucopolysaccharidoses. Macroglossia may result in respiratory compromise, dysphagia, and poor cosmesis.[113] Macroglossia is also a feature of lingual vascular anomalies (Fig. 29-41). The enlargement of the tongue that accompanies these lesions is sometimes also associated with ulceration and hemorrhage. Imaging is not usually required for evaluation of macroglossia per se unless an underlying primary lesion (e.g., vascular anomaly) is suspected. However, dynamic imaging of macroglossia as part of the assessment of obstructive sleep apnea is sometimes required.

Glossoptosis is a term used to describe posterior displacement of the tongue. This phenomenon has been

FIGURE 29-38 Dermoid cyst in the floor of the mouth in a young child with a palpable neck mass. The midline neck mass is low density, nonenhancing, and indistinguishable from the more common thyroglossal duct cyst. If fat globules are seen within such a mass, the diagnosis of dermoid cyst can be made preoperatively.

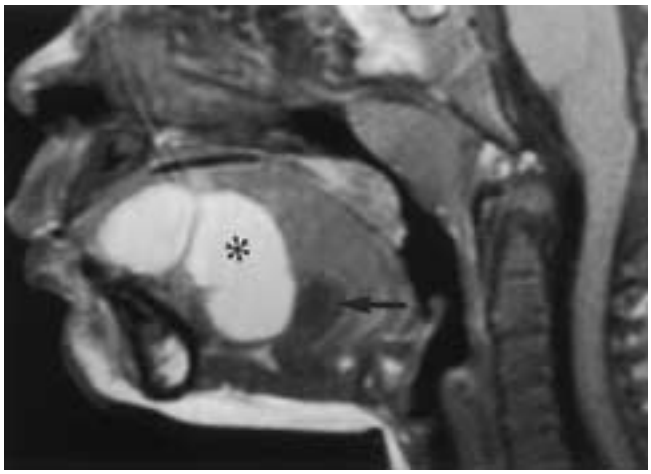
FIGURE 29-39 Primitive foregut cyst in a baby with a congenital tongue mass. Midline contrast-enhanced, fat-suppressed sagittal T1-weighted image shows a rounded, unilocular, sharply circumscribed cyst (c) located within the anterior third of the tongue. Note that the lesion is indistinguishable from the dermoid cyst shown in Figure 29-37.

observed in patients with macroglossia, micro- or retrognathia, and neuromuscular disorders and, in a minority of cases, in otherwise healthy patients.[14]

Micrognathia and Retrognathia

An abnormally small mandible is termed micrognathia. Abnormal posterior placement of the mandible is called retrognathia. There is often a combination of micro- and retrognathia (Figs. 29-42 and 29-43). Abnormal growth or position of the mandible can be caused by malformation, deformation, or connective tissue dysplasia.[114] The Robin sequence or complex (previously termed *Pierre Robin syndrome*) is characterized by micrognathia and/or retrognathia, glossoptosis, a wide U- or V-shaped cleft palate, and upper airway obstruction (Fig. 29-42). Factors that contribute to airway obstruction in the Robin sequence include micrognathia/retrognathia, glossoptosis, abnormal movement of the lateral pharyngeal wall, and sphincteric pharyngeal constriction.[115] The Robin sequence/complex is etiologically, phenotypically, and pathologically heterogeneous and occurs in syndromic and nonsyndromic forms.[114] Numerous monogenic, chromosomal, teratogenic, deformational (amniotic band disruption), and idiopathic syndromes are associated with Robin sequence. The most frequently encountered of these are the Stickler syndrome (hereditary arthro-opthalmopathy), deletion 22q11.2 syndrome (velocardiofacial syndrome), and Treacher Collins syndrome.[114, 116] In deletion 22q11.2 syndrome, the mandible is essentially normal in size but retrognathic as a result of an abnormally obtuse cranial base angle.[117] Also known as velocardiofacial syndrome, this autosomal dominant disorder is characterized by cleft palate, cardiac defects, learning disabilities and a typical facial appearance.[118] Less frequently, patients have manifestations of the DiGeorge complex including hypocalcemia, hypoplastic or absent lymphoid tissue, and T-cell deficiency.[119] This syndrome is also associated with medially positioned, tortuous, or kinked internal carotid arteries, low common carotid bifurcations,



VIEW IMAGE

and hypoplastic vertebral arteries.[120, 121] It is important to recognize this potentially dangerous implication, as pharyngoplasty for velopharyngeal incompetence and hypernasal speech may potentially damage the anomalous internal carotid arteries.[122]

Oculo-auriculo-vertebral spectrum encompasses a heterogeneous group of disorders ranging from minor unilateral ear anomalies or preauricular tags to severe manifestations with anotia, micrognathia, orbital dystopia, cervical spine anomalies, and ocular dermoids.[123] Terminology used to describe entities within this spectrum includes the first and second branchial arch syndrome, hemifacial microsomia, Goldenhar syndrome, and craniofacial dysplasia. In contrast to the Robin sequence, manifestations are typically asymmetric and usually unilateral. Airway abnormalities are produced by a combination of asymmetric micrognathia or hemimicrognathia, maxillary hypoplasia, and velopharyngeal insufficiency.[123] Asymmetric palatal and lateral pharyngeal wall motion have been attributed to unilateral hypoplasia of the pharyngeal constrictors and other pharyngeal muscles.[124] The structural abnormalities involving the pharynx and larynx predispose to obstructive sleep apnea and difficulties with intubation.[123]

Imaging modalities for airway assessment in children with micro- or retrognathia include cephalometrics, videofluoroscopy, CT, and MR imaging. If the patient is unable to tolerate the examination without sedation, a general anesthetic may be required. Cephalometrics are plain radiographs that are used to analyze the facial proportions based on specific osseous landmarks. Thin-section high-resolution helical CT with 2D (Fig. 29-42) and 3D reformatting provides multiplanar information including the size and proportions of the maxilla, nose, and mandible and the dimensions of the airway (Fig. 29-44). Two-dimensional sagittal reformatted images are useful for assessment of the vertical height of the pharynx, which may be reduced in children with coexistent spinal anomalies (oculo-auriculovertebral spectrum). The images should also be assessed for cranial base, temporal bone, and cervical spine anomalies as indicated by the clinical diagnosis. Patients with 22q11.2 syndrome who require pharyngeal flap surgery should undergo preoperative vascular imaging (CT angiography or 2D time-of-flight MR angiography) precisely to document the presence and location of anomalous internal carotid arteries in relation to the flap donor site.[121, 122]

LARYNGEAL OBSTRUCTION

Laryngomalacia

Laryngomalacia is a disorder characterized by an abnormal redundancy of supraglottic tissue.[125] Laryngomalacia is the most common cause of stridor in the newborn and infant. The stridor is characteristically high-pitched and inspiratory and is most severe in the supine position.[30] The etiology is thought to be related to delayed development of neuromuscular control of the airway.[126] Laryngomalacia is usually a benign self-limited condition that typically presents within the first 2 weeks of life, often resolves by 2 years of age, and seldom requires surgical intervention.[125] It has been associated with other causes of airway obstruction, cardiovascular anomalies, gastroesophageal reflux, and neurologic deficits.[127]

In assessing children with laryngomalacia, pertinent clinical and anatomic information should be obtained. Clinical features include the severity of stridor, presence of synchronous airway lesions, failure to thrive, prematurity, age at presentation, and associated cardiovascular, neurologic, chromosomal, or syndromic abnormalities.[127] Fluoroscopy or plain radiographs obtained during inspiration show inferior and medial bowing of the arytenoids, aryepiglottic folds, and epiglottis, with ballooning of the laryngeal ventricle and hypopharynx. Definitive anatomic information is provided by fiberoptic examination. Flexible laryngoscopy may be used to confirm the diagnosis and assess the anatomy. Rigid endoscopy is reserved for selected cases in which the cause of stridor is cryptic, additional airway lesions are suspected, or operative management is planned. On direct laryngoscopic examination, laryngomalacia has been classified using anatomic factors as posterolateral, posterior, or anterior.[125] Posterolateral collapse is due primarily to redundant aryepiglottic folds, posterior collapse to excess arytenoid mucosal or cartilaginous bulk, and anterior collapse to excess pliability of the epiglottis.

Vocal Cord Paralysis

Vocal cord paralysis (VCP) is the second most common cause of stridor in infancy.[128] Bilateral VCP is usually central in origin, and unilateral paralysis typically has a peripheral cause. VCP can be congenital or acquired. Bilateral VCP is rarely seen in an otherwise normal child.[30] Brainstem malformations, particularly the Chiari II malformation, are the most common cause of VCP in children.[129] These children present with nonprogressive, high-pitched inspiratory stridor and usually have bilateral paralysis. Although the paralysis is probably multifactorial in etiology, possible mechanisms are mechanical traction on the vagus nerves from caudal displacement of the cerebellum and/or hindbrain herniation, congenital dysplasia of the brainstem, and lack of afferent information from the carotid bodies.[128] Other associated conditions include perinatal hypoxic ischemic injury, as well as multiple other disorders of the central and peripheral nervous systems. VCP can also be seen in conjunction with other congenital anomalies such as cardiac or pulmonary malformations, as well as other associated laryngeal malformations such as clefts or stenosis.[128, 130]

Unilateral VCP is most commonly left-sided and is seen in children with congenital cardiac anomalies, following tracheoesophageal fistula repair or corrective surgery for congenital heart disease, and following trauma, particularly traumatic delivery.[126]

VCP can affect any or all of the normal laryngeal functions, resulting in voice changes, stridor, feeding difficulties, ineffective cough, aspiration, and recurrent pneumonia.[131]

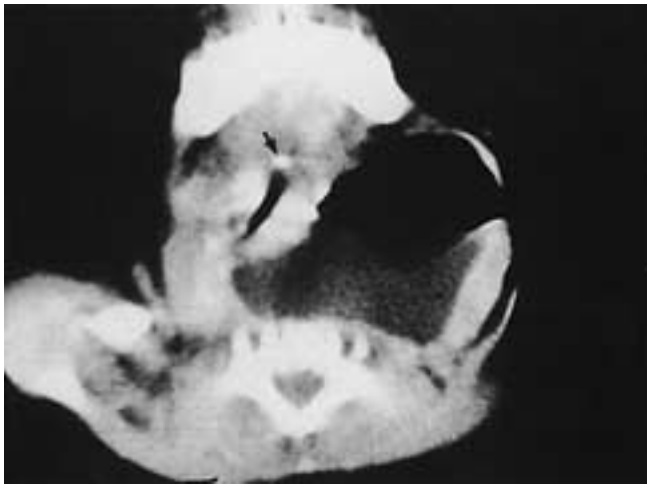
The investigation of choice for the evaluation of vocal

Copyright © 2003, Mosby, Inc. All rights reserved.

cord paralysis is flexible laryngoscopy.[128] Adjunctive techniques include airway fluoroscopy, CT, and MR imaging. Airway fluoroscopy shows limited abduction of the paralyzed vocal fold with respiration or crying. With unilateral paralysis, the AP film reveals thinning of the paralyzed cord, which may appear lower than the normal cord, the laryngeal ventricle is usually capacious, and the ipsilateral pyriform sinus may be larger than that on the normal side. If the lateral plain film is obtained during phonation, two separate air-filled laryngeal ventricles may be seen, the ventricle on the paralyzed side being lower and usually larger than the ventricle on the normal side.[132] MR imaging of the brain, posterior fossa, and skull base is important in the evaluation of bilateral paralysis to delineate posterior fossa malformations, hydrocephalus, posterior fossa tumors with cerebellar tonsillar herniation, and craniocervical malformation. Chest radiographs and a barium swallow may show anomalies of the heart, mediastinum, or great vessels as an explanation for unilateral VCP. CT or MR imaging of the neck may be required to trace the entire course of the vagus nerve from the skull base to the mediastinum in order to exclude a neoplasm as a source of vagal or recurrent laryngeal nerve dysfunction.

Laryngoceles and Laryngeal Cysts

A laryngocele is an air- or fluid-filled dilation of the laryngeal saccule that communicates with the laryngeal ventricle and is a rare cause of airway obstruction in infants.[133, 134] An internal laryngocele remains within the boundaries of the supraglottic laryngeal superstructure, and an external laryngocele, or combined laryngocele, the most common type, extends through the thyrohyoid membrane and has both an internal and an external component. Plain films are often nonspecific, showing a supraglottic airway mass. However, an air collection in the lateral neck, projected over the supraglottic larynx, is a highly suggestive finding. The external or combined laryngocele may present as a fluctuating soft lateral neck mass, and cross-sectional imaging shows the internal component submucosally filling the paraglottic space and obliterating the fat, and the external component extending through the thyrohyoid membrane into the lateral neck (Fig. 29-45). The CT density or the MR signal intensity of the laryngocele is variable, depending on whether the cyst is filled with air, fluid, or proteinaceous debris. Definitive therapy for laryngocele is excision.[133]



VIEW IMAGE

VIEW IMAGE

In general, laryngeal cysts include a variety of lesions with different histogenetic origins and diverse symptoms related to their site and size. A recent classification system has been proposed that incorporates the genesis and development of laryngeal cysts and subdivides cysts into congenital cysts, retention cysts, and inclusion cysts.[135] Although encountered anywhere in the larynx, laryngeal cysts are fluid-filled and are most frequently found in the vallecula and true vocal cords.[136] Plain films show a smooth mass projecting into the airway (Fig. 29-46). Typically on CT, laryngeal cysts are well-circumscribed, submucosal, low-density, nonenhancing masses. On MR imaging the signal intensities vary. The T1-weighted signal intensity is usually low (water) but may be high (infection or hemorrhage), and the T2-weighted signal intensity is high. Treatment for laryngeal cysts is endolaryngeal microsurgery with marsupialization of the cyst.[135]

Anomalies of the Epiglottis

Anomalies of the epiglottis are extremely rare and include congenital absence of the epiglottis and bifid epiglottis. Clinical symptoms include aspiration and/or airway obstruction.[137] Bifid epiglottis has been reported in association with other laryngeal anomalies and in a syndromic form with other congenital anomalies, most often with polydactyly.[138] Pallister-Hall syndrome consists of polydactyly, hypothalamic hamartoma, imperforate anus, and absent or hypoplastic epiglottis with a laryngeal cleft.[139, 140] The diagnosis of epiglottic anomalies is made endoscopically. Radiologic investigation is indicated for assessment of other organ systems in children who have syndromic features.

Laryngeal Webs, Clefts, and Atresia

A laryngeal web is a membrane that partially occludes the airway lumen and results from failure of recannulation during embryogenesis.[141] Although laryngeal webs may occur anywhere in the larynx, most are at the glottic level, usually involving the anterior commissure. Presenting signs depend on the location and the degree of airway obstruction and may include stridor, hoarseness, weak voice, or feeding difficulties.[142] Endoscopy is the mainstay of diagnosis, but plain films may occasionally show a web of tissue within the airway.

Laryngeal clefts are rare anomalies that present with stridor and aspiration.[143] Although the diagnosis is usually made endoscopically, an esophagogram may show tracking of contrast from the upper esophagus into the trachea (Fig. 29-47). A Type I cleft is confined to the level of the interarytenoid space above the level of the vocal folds. A partial cricoid cleft is classified as Type II. Type III and IV lesions traverse the cricoid completely.[144]

Laryngeal atresia may occur at the supraglottic or glottic level and is extremely rare. Imaging plays little role in the postnatal management of this condition, as survival is unlikely unless the lesion is immediately recognized and emergent tracheotomy performed. However, laryngeal atresia has been diagnosed with antenatal sonography obtained during the second trimester with coronal images of the upper neck.[145] Images obtained during fetal breathing demonstrate the stenotic larynx in a closed position, and color Doppler fails to show movement of fluid across the atretic larynx. Additional sonographic features in the fetus with complete or near-complete upper airway obstruction include large echogenic lungs, flattened or inverted diaphragms, dilated airways distal to the obstruction, and fetal ascites and/or hydrops.[4] The fetus with laryngeal atresia should be carefully screened for coexistent anomalies of the central nervous system, renal anomalies, and esophageal atresia or fistula.[145] For isolated laryngeal atresia without significant hydrops, survival depends upon therapeutic maneuvers to bypass the site of airway obstruction while the fetus remains connected to the placenta. Antenatal diagnosis of laryngeal atresia may permit the implementation of the planned ex utero intrapartum treatment (EXIT) procedure, with immediate laryngoscopy and placement of a tracheostomy.[146]

SUBGLOTTIC OBSTRUCTION

Congenital Subglottic Stenosis

Congenital subglottic stenosis is the third most common congenital laryngeal abnormality and is the most common lesion requiring tracheotomy in infants under 1 year of age.[142] Symptoms include biphasic or inspiratory stridor and a barking cough in the absence of a history of prior intubation or other cause of acquired subglottic stenosis. Congenital subglottic stenosis may be isolated or may be associated with congenital syndromes, especially trisomy 21, in which case the entire larynx is small.[141] Among infants with congenital subglottic stenosis, 7% to 10% have other laryngotracheal anomalies such as tracheoesophageal fistula, vocal cord paralysis, or tracheal stenosis.[147] The stenosis is usually associated with a small or malformed cricoid cartilage, with or without thickening of the underlying submucosal layer.[148]

The diagnosis of congenital subglottic stenosis is suggested on plain films and confirmed by endoscopy. Plain films show symmetric circumferential subglottic narrowing, the typical hourglass appearance. This narrowing extends for 1 to 1.5 cm and is fixed, not changing with the phase of respiration.[149] The diagnosis is considered when a 4 mm

Copyright © 2003, Mosby, Inc. All rights reserved.

scope or an age-appropriate-sized endotracheal tube cannot pass through the subglottic larynx in an infant who has not been intubated previously.[150] The lesion is generally self-limited, resolving with laryngeal growth.[151] However, if symptoms are severe, anterior laryngotracheal decompression (anterior cricoid split), laryngotracheal reconstruction, or tracheostomy may be required.[148]

TRACHEAL OBSTRUCTION

Tracheal anomalies associated with obstruction of the airway include agenesis or atresia of the trachea, fibrous strictures, stenoses and webs, and absence or deformity of the tracheal cartilages.[152] Stenotic lesions of the trachea can also be classified as causing intrinsic compression, extrinsic compression, or both. Intrinsic tracheal narrowing due to absence or deformity of tracheal cartilages incorporates tracheomalacia, tracheal deformity due to vascular compression, and tracheal cartilage anomalies. Conditions that produce both extrinsic and intrinsic narrowing include aberrant vessels and tracheoesophageal anomalies.

Tracheomalacia

Primary tracheomalacia is a rare entity due either to a deficiency of cartilage with increased width of the posterior membranous tracheal wall or to mechanical weakness that results in partial or total collapse of the airway and respiratory embarrassment.[153] Patients may experience stridor, wheezing, chronic cough, anoxic spells, and failure to thrive.

Endoscopic evaluation is used to provide a diagnosis, assess the severity of tracheomalacia, and exclude other lesions.[153] Airway fluoroscopy can also be used to confirm tracheomalacia in a symptomatic child when the tracheal diameter decreases more than 50% during expiration compared with the diameter during inspiration.[154] The change in diameter during a respiratory cycle helps differentiate tracheomalacia from a fixed stenotic lesion (Fig. 29-48).

Tracheomalacia usually resolves spontaneously by the second year of life.[152] However, severely symptomatic children may require treatment with continuous positive airway pressure, placement of an endotracheal stent, surgical resection, or the ''pexy'' procedure.[153, 155]

Intrinsic Tracheal Stenosis

Intrinsic tracheal stenosis can be congenital or acquired. Congenital tracheal stenosis results from one or more complete cartilaginous tracheal rings, with absence of the posterior membranous portion of the trachea that produces a circular cross section of the trachea.[156] Tracheal rings generally produce one of three types of tracheal stenosis: segmental stenosis with an hourglass configuration of the trachea, a funnel-shaped trachea with progressive tracheal narrowing from the cricoid to the carina, and narrowing of

FIGURE 29-49 Congenital tracheal stenosis in a 2½-year-old boy with stridor. **A**, Axial spiral CT scan obtained immediately below the endotracheal tube shows a central venous line (*arrow*) and a nasogastric tube in the esophagus (*E*). The posterior membranous portion of the trachea is not flat but has a rounded contour (curved arrow). **B**, Two-dimensional coronal reformatted image shows the extent of the tracheal narrowing.

the entire trachea.[157, 158] Extensive malformation with a solid cartilaginous cylinder in place of the normal trachea has been termed *tracheal cartilaginous sleeve*.[159] This rare anomaly is often associated with other abnormalities, usually the syndromic forms of craniosynostosis such as Apert, Crouzon, and Pfeiffer syndromes.[87, 158, 160] Complete tracheal rings are also associated with other bronchial, vascular, cardiac, or intestinal abnormalities, tracheoesophageal fistula, eophageal atresia, and the VATER syndrome or complex (vertebral defects, anal atresia, tracheoesophageal fistula, esophageal atresia, renal anomalies, and aplasia of the radius).[156]

Clinical presentation of tracheal stenosis ranges from largely asymptomatic to symptoms such as stridor, increased mucus production, croup, sporadic cyanosis, and increased numbers of respiratory infections. Endoscopic evaluation reveals a smooth tracheal surface. Plain films may be normal and may underestimate the narrowing or show a narrowed tracheal air column. Cross-sectional imaging shows a rounded appearance of the trachea instead of the normal posterior membranous flattening (Fig. 29-49). CT is superior to high-kilovoltage plain films and chest radiography in evaluating the presence and extent of stenosis, and is sometimes superior to endoscopy for depicting the distal extent of disease.[161] Helical CT with 3D reconstruction provides excellent anatomic delineation of tracheobronchial anatomy and is safer and less invasive than conventional tracheobronchography (Fig. 29-50).[162]

Prognosis and treatment depend on the degree and extent of stenosis, with more severely affected infants requiring early surgical intervention. Surgical options include balloon dilatation, tracheostomy, tracheal resection and primary anastomosis, tracheoplasty, or tracheal stenting.[156]

Vascular Compression of the Airway

Vascular causes of tracheal stenosis include innominate artery compression, aortic arch anomalies, aberrant left pulmonary artery, and anomalous right subclavian artery.

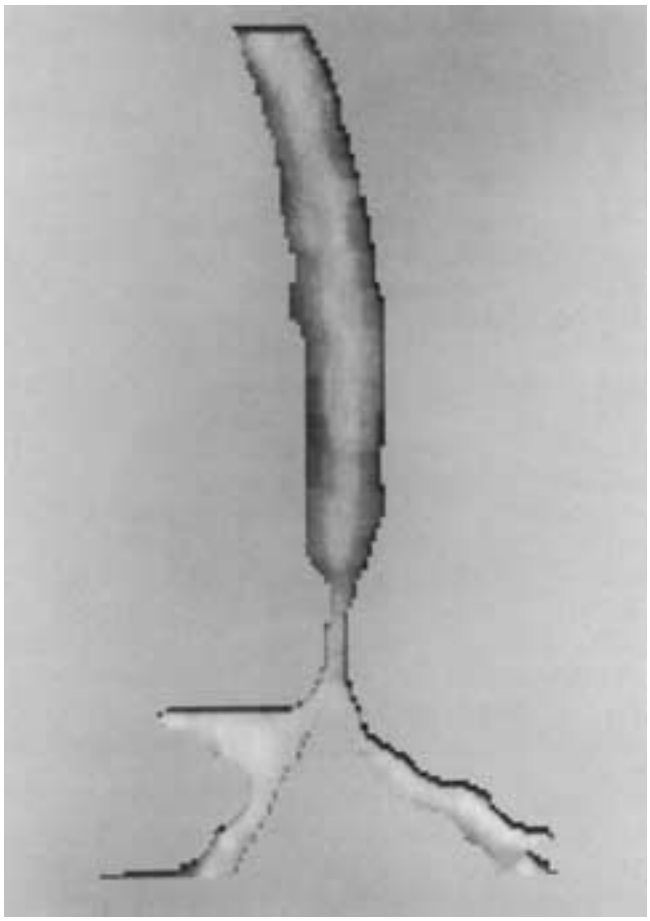

FIGURE 29-50 Tracheal stenosis in a newborn with stridor. Three-dimensional reconstructed images of the trachea and carina were obtained using a segmentation technique. T1-weighted axial images were obtained of the airway, and then coronal reformations confirmed the tracheal narrowing and best showed the cranial-caudal extent of the luminal compromise. The length of the narrowing was not appreciated at endoscopy because the endoscope could not pass through the narrowed segment.

Variations of normal vascular anatomy that can cause airway compression have an incidence of approximately 3%.[9] The most frequent presenting complaint is stridor, which is sometimes aggravated by agitation, feeding, or exertion. Other symptoms include episodic apnea, reflex apnea, croupy cough, recurrent respiratory tract infections, and dysphagia.[9] Mildly symptomatic cases can be managed conservatively. Surgical management is required for a variety of absolute and relative indications.

Historically, many aortic arch and great vessel anomalies were diagnosed by a characteristic combination of great vessel location on plain films, lateral deviations of the trachea and esophagus, indentation of the trachea, and rounded or oblique defects in the contour of the esophagus on barium swallow.[163] Based on plain films and esophagograms, four imaging patterns and their implications have been described: (1) anterior tracheal and posterior esophageal indentation: vascular ring; (2) normal trachea with posterior esophageal indentation: aberrant subclavian artery; (3) posterior tracheal and anterior esophageal indentation: pulmonary sling; and (4) anterior tracheal indentation, normal esophagus: innominate artery compression.[164] It is important to note that any vascular anomaly causing tracheal stenosis can be associated with tracheoesophageal fistulas or other forms of tracheal stenosis such as complete tracheal rings that should be diagnosed prior to any definitive surgical procedure.[153] More recently, MR imaging has become the imaging modality of choice to depict vascular anatomy and to exclude other forms of extrinsic tracheal compression such as mediastinal masses.[9] MR images are acquired using respiratory compensation techniques and cardiac gating, with data acquisition primarily during expiration.[154] Both 2D and 3D reconstructed images are useful for illustrating the degree of compression and the relationship of the extrinsic structures to the trachea (Figs. 29-51B,C, 29-52, and 29-53). Helical CT angiography has also been utilized and rapidly provides diagnostic images. For patients who are unable to suspend respiration, adequate images can generally be obtained during quiet breathing. Limitations of this technique include, in addition to exposure to ionizing radiation, inability to define nonenhancing ligamentous structures and appropriate timing of contrast injection.[165] Multidetector CT imaging may offer potential in terms of improved image quality and decreased exam time, but with an increased dose of radiation relative to older single-slice scanners.[166]

Vascular compression of the trachea is most frequently caused by the innominate artery.[153, 163] The anterior tracheal wall is compressed by the vessel as it crosses from left to right.[167] Possible etiologic factors implicated in symptomatic tracheal compression by the innominate artery include a more distal take-off from the aortic arch, increased tautness of the innominate artery, more compliant tracheal cartilages, and mediastinal crowding from enlargement of other neighboring structures.[9, 153] The diagnosis is controversial because normal children without clinical evidence of airway compromise may have, on fluoroscopy or plain films, prominent anterior tracheal impression at the level of the innominate artery.[168]

The most common symptomatic true vascular ring is the double aortic arch (Figs. 29-51 and 29-52).[169] A right-sided aortic arch associated with a left ductus or aberrant left subclavian also forms a complete vascular ring that produces less constriction than a double aortic arch (Fig. 29-53).[170]

The aberrant right subclavian artery occurs in approximately 1 in 200 persons.[9] The vessel originates from the aorta caudal to the origin of the left subclavian artery and courses posterior to the esophagus, producing dysphagia but seldom symptomatic airway compromise.

Pulmonary artery sling is an uncommon but typically symptomatic noncircumferential vascular variant in which the left pulmonary artery originates from the posterior aspect of the right pulmonary artery, compresses the right mainstem bronchus, and passes between the trachea and esophagus to reach the hilum of the left lung.[170] The combination of complete tracheal rings with a pulmonary artery sling is known as the *ring-sling complex*.[171]

VASCULAR ANOMALIES

The Mulliken and Glowacki classification is a biological classification of vascular anomalies that separates the vascular anomalies into two major categories: true vascular tumors (e.g., hemangioma and kaposiform hemangioendothelioma) and vascular malformations.[172] This distinction is clinically useful and guides the choice of appropriate therapy. Rapid growth, endothelial proliferation, and hyperplasia characterize vascular tumors such as hemangioma. Vascular malformations are nonproliferating lesions that consist of dysplastic vascular channels and are classified according to their dominant component and hemodynamic features. Slow-flow lesions include capillary malformations (CMs), venous malformations (VMs), and lymphatic malformations (LMs). High-flow malformations are arterial lesions (e.g., arteriovenous fistulae [AVFs], arteriovenous malformations [AVMs]). There are also complex malformations that contain a combination of elements. Malformations grow commensurate with the patient or expand secondary to hemodynamic alteration.

Hemangioma

Hemangiomas typically arise postnatally during the first few months of life, although true congenital tumors do occasionally occur.[173] Females are affected twice as often as males.[174] Hemangiomas proliferate during the first year of life and then involute during the ensuing several years. Subglottic hemangiomas produce hoarseness and biphasic stridor with potentially life-threatening respiratory compromise (Figs. 29-54 and 29-55).[175] The acronym PHACES has been proposed to emphasize an occasionally encountered association of the following characteristic features: *p*osterior fossa malformations, *h*emangiomas, *a*rterial anomalies, *c*oarctation of the aorta and cardiac defects, *e*ye abnormalities, and *s*ternal malformations.[176, 177]

In subglottic hemangioma, radiologic examination with AP plain films shows subglottic narrowing, classically asymmetric, unlike the concentric symmetric narrowing of congenital subglottic stenosis (Fig. 29-54A).[141, 178] However, 50% of the time the subglottic narrowing may be symmetric.[179] The lateral film shows a subglottic mass. On CT, hemangiomas appear as lobulated solid tumors that are

VIEW IMAGE

isodense with muscle and enhance rapidly and intensely following the administration of contrast (Fig. 29-54B). During the proliferative phase, MR imaging reveals a lobulated, moderately hyperintense mass on T2-weighted images (Fig. 29-55), with intense enhancement on contrast-enhanced, T1-weighted sequences (Fig. 29-56). Prominent vascularity within the tumor appears as flow voids on spin-echo pulse sequences (Fig. 29-55) and flow-related enhancement on short echo-time gradient-echo images. The presence of a parenchymal mass differentiates hemangioma from the other high-flow vascular anomalies such as AVM, which may exhibit reactive soft-tissue changes but no discrete mass. The enhancement pattern and vascularity differentiate the high-flow, enhancing hemangioma from the low-flow, nonenhancing lymphatic malformation. The vascularity and early enhancement may help to differentiate hemangioma from venous malformation. However, characteristic imaging features may not be as easily observed with small hemangiomas. Involuting hemangiomas enhance less intensely, have diminishing vascularity

over time, and have an increasing proportion of fibrofatty matrix.

Hemangiomas that do not interfere with vital functions can be managed expectantly, anticipating involution. However, medical treatment with antiangiogenic drugs such as steroids or alpha interferon, embolization, surgical resection, and sometimes tracheostomy may be required to treat or support patients with hemangiomas that interfere with vital functions such as breathing. Subglottic hemangiomas are also amenable to endoscopic ablation with laser therapy.[180, 181]

Lymphatic Malformation

Lymphatic malformations (LMs) are cystic masses composed of dysplastic endothelium-lined lymphatic channels filled with protein-rich fluid. LMs may be detected antenatally but usually present at birth or within the first few years of life. The usual mode of presentation is the presence of a mass and/or alteration of function from mass effect. However, these anomalies may remain clinically silent until sudden enlargement occurs as a result of hemorrhage or infection. LMs may obstruct the airway, and tracheostomy may be required. Skeletal distortion and overgrowth is a typical feature of LMs.[182] Most LMs are sporadic, but the malformation can occur as part of generalized disorders such as Turner syndrome (45XO), Noonan syndrome, trisomy 21, trisomy 13, and trisomy 18.[183, 184]

LMs can be characterized based on the size of the cysts as microcystic, macrocystic, or mixed. On clinical examination, a localized cystic mass or a solid or spongy mass is palpated or there may be diffuse infiltration and enlargement of the affected region. Macroglossia and overgrowth of the mandible with dental malocclusion can also occur. The most frequent complications of LMs are infection and hemorrhage.

The choice of imaging modality for LMs depends on the information required. MR imaging produces superior soft-tissue contrast and tissue characterization and is generally considered the imaging modality of choice in diagnosing and demonstrating the extent of LMs. However, where the clinical diagnosis of macrocystic LM is known, ultrasound or CT will adequately delineate the extent of the lesion in most cases (Fig. 29-57A). The appearance of LM on imaging depends on the size of the lymphatic spaces and on the presence of hemorrhage or infection (Fig. 29-57). LM has a tendency to involve multiple fascial compartments. The lesions generally appear cystic and septated. A very characteristic feature of LMs is the presence of fluid-fluid levels (Fig. 29-58). Large and/or anomalous adjacent venous channels are often seen, and communication between the LM and adjacent veins is frequently present.[185]

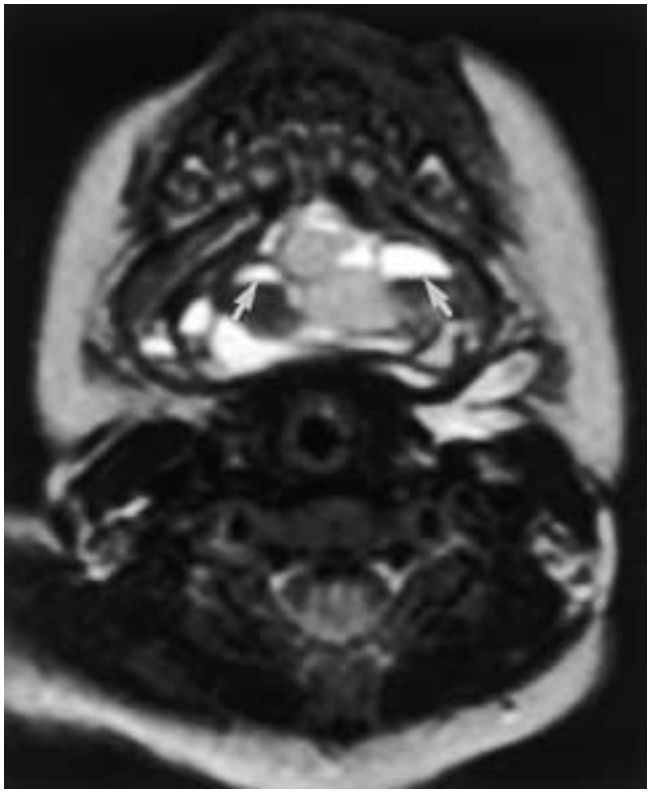
FIGURE 29-57 LM complicated by infection and subsequent hemorrhage in a 3-year-old boy. **A**, Axial contrast-enhanced CT reveals a low-attenuation macrocystic LM (*L*) encroaching on the airway (*straight arrow*). There is enhancement only of the margins and septations of the LM. Note the deformity and remodeling of the right mandibular ramus (*curved arrow*). This is a relatively common feature of LMs. **B**, Axial T1-weighted MR image reveals variegated high and intermediate signal intensity representing hemorrhage within the macrocystic LM (*asterisks*). The LM distorts and compresses the oropharynx (*arrow*).



VIEW IMAGE

FIGURE 29-58 LM in a young boy. Axial FSE T2-weighted MR image demonstrates fluid-fluid levels (*arrows*) that are characteristic of LM.

Sonography of a macrocystic LM reveals a uni- or multilocular cystic mass sometimes containing echogenic debris. Microcystic LMs appear hyperechoic because of numerous interfaces.

Uncomplicated LMs usually appear hypodense on CT (Fig. 29-57) and markedly hyperintense on T2-weighted MR images. However, the density on CT, the signal intensity on MR imaging, and the presence of fluid-fluid levels vary, depending on the protein content and the presence of blood products. Depending on the time interval since hemorrhage, blood breakdown products produce T1 and T2 shortening or T2 prolongation on MR imaging (Figs. 29-57B and 29-58). Following the administration of contrast, the cyst walls/septations enhance but the fluid contained within the cystic space does not enhance (Fig. 29-57).

If a multicystic neck mass is diagnosed by antenatal ultrasound, fetal MR images can be obtained for diagnostic purposes and to provide further anatomic information including airway assessment. The half-fourier single shot turbo spin-echo (Haste) or the single-shot fast spin-echo (SSFSE) pulse sequence has been favored for delineation of masses and decreased motion artifacts.[186] The main differential diagnosis for multiseptated macrocystic lesions is teratoma in the fetus or newborn and venous malformation. The presence of fluid-fluid levels, lack of fluid enhancement, and absence of phleboliths differentiate LM from venous malformation. The absence of fat or calcification within the lesion differentiates LM from teratoma. Microcystic LMs produce more of a diagnostic dilemma, as

Copyright © 2003, Mosby, Inc. All rights reserved.

the cystic spaces may be so small that the lesion appears more diffusely enhancing.

The treatment of LMs includes the administration of antibiotics for infection and surgical resection. Postoperative complications and residual or recurrent disease are common. Intralesional injection with sclerosants such as ethanol or OK 432 may provide local control of the lesion in inoperable cases.[175, 187]

Venous Malformation

Venous malformations (VMs) are vascular malformations that consist of dysplastic venous channels. VMs are present at birth, but the age of presentation depends on size, location and interference with normal function. VMs grow proportionately to the child and frequently enlarge during puberty.[175] Clinical manifestations include pain and swelling, especially after recumbency. Clinical examination typically reveals blue or purplish discoloration of the skin and a soft or spongy, compressible mass that expands with the Valsalva maneuver or with dependent positioning.[185] VM can be single or multifocal and localized or extensive. Phlebothrombosis produces pain and a mass that is firm to palpation. Familial forms of VM include *Blue-rubber bleb nevus syndrome* (cutaneous and gastrointestinal VMs), *familial multiple glomangioma* (glomus cells line VM channels), and *cerebral cavernous malformations* (with or without cutaneous lesions).[175] Mafucci syndrome is characterized by multiple enchondromas associated with venous anomalies.

The characteristic imaging feature of VMs is the development of phleboliths associated with phlebothrombosis. Phleboliths appear as rounded, lamellated, calcific densities on CT. The fluid within VMs is venous blood that enhances, unlike the lymph contained within LMs. Early CT or MR images acquired during or immediately after bolus administration of IV contrast demonstrate enhancement of the VM that is initially heterogeneous. Delayed images show a more homogeneous pattern of enhancement (Fig. 29-59). MR imaging demonstrates some imaging similarities with LMs in that VMs are cystic and septated, and the fluid within the cystic spaces is markedly hyperintense on long TR images. Phleboliths appear as circumscribed signal voids (Fig. 29-59B) that should not be confused with flow voids. Unlike proliferating hemangiomas, arterial or rapid flow on flow-sensitive pulse sequences is not a feature of VMs. However, MR venography may reveal dilated or anomalous veins in the vicinity of VMs.

It is important, from a therapeutic standpoint, to differentiate VM from hemangioma or LM. The term *cavernous hemangioma* should be avoided when referring to VMs, as it is erroneous and frequently leads to the institution of inappropriate antiangiogenic drug therapy and subsequent therapeutic failure.[185] The treatment of VMs includes the use of elastic compressive garments, aspirin, percutaneous sclerotherapy, and surgical resection.[175, 185] Direct percutaneous cannulation with contrast injection of the VM typically shows interconnecting sinusoidal spaces and adjacent normal or dilated venous channels (Fig. 29-60).[185] For extensive VM of the airway, staged therapy with a combination of sclerotherapy and photocoagulation has been advocated.[188]

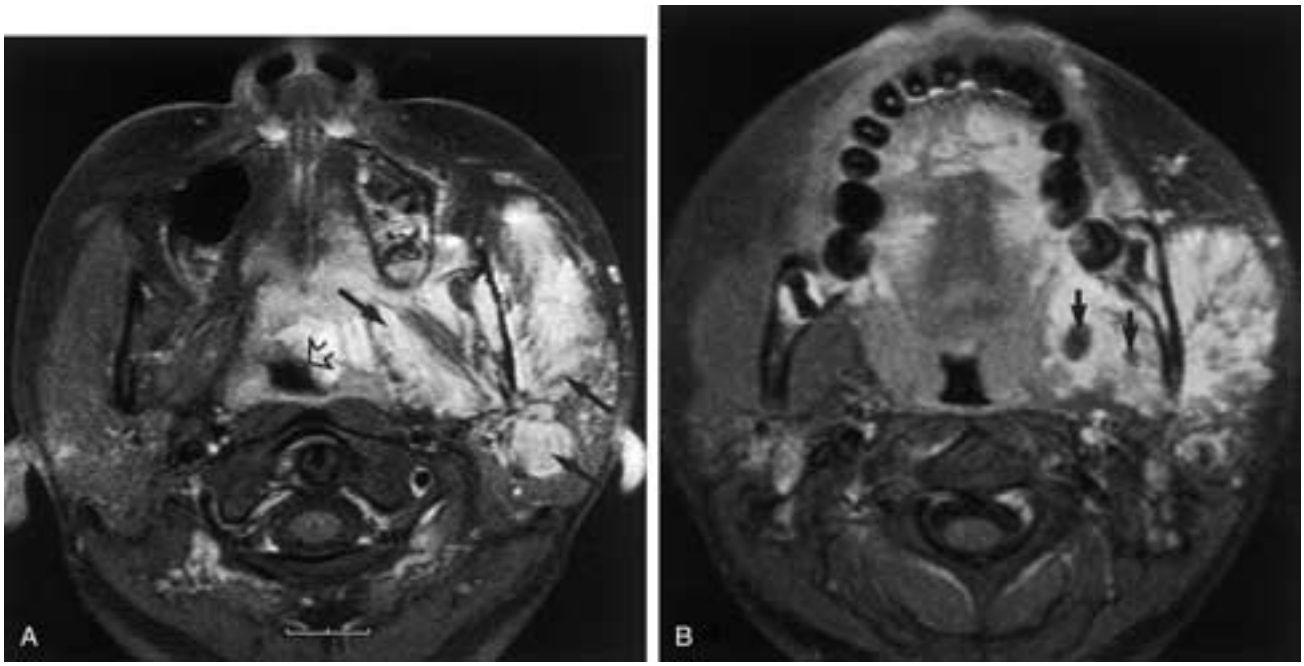


FIGURE 29-59 VM in a 13-year-old girl. Axial fat-suppressed, contrast-enhanced T1-weighted MR image (**A**) reveals a multiseptated enhancing mass (*arrows*) within the left muscles of mastication, the mandible, parotid space, parapharyngeal space, soft palate, and pharynx. There is distortion of the airway (*open arrow*). **B**, Phleboliths (*arrows*) are present.

SECTION SIX

INFECTIOUS AND INFLAMMATORY DISORDERS

VIRAL ADENOTOSILLITIS AND LYMPHADENOPATHY

Nonspecific Viral Infection

Infections of the head and neck generally produce reactive enlargement of lymphoid tissue (adenoids, tonsils, and lymph nodes). Inflammatory adenotonsillitis with lymphadenopathy may be viral or bacterial in origin. Viral illnesses, with the exception of the acquired immunodeficiency syndrome (AIDS), are generally self-limited and do not usually require imaging. Mucocutaneous candidiasis, parotid enlargement, and cervical adenopathy have been reported in pediatric patients with AIDS, but imaging of the airway is not usually necessary.[189]

Infectious Mononucleosis (Epstein-Barr Virus)

Massive adenopathy with adenotonsillitis, fever, weakness and malaise, typically presenting in a teenager, is characteristic of infectious mononucleoisis, caused by the Epstein-Barr virus (EBV). Unlike other viral illnesses, EBV infection may produce massive, protracted enlargement of lymphoid tissues, sometimes with life-threatening compromise of the airway. In this situation, imaging is sometimes required to exclude secondary bacterial infection with abscess formation. CT with contrast demonstrates massive enlargement and enhancement of lymphoid tissues. The enlarged adenoids sometimes display streaky heterogeneous enhancement with interspersed low attenuation, indicative of adenoidal edema (phlegmonous change) (Fig. 29-61). This appearance should not be mistaken for abscess formation. An indistinguishable appearance can be seen in severe streptococcal pharyngitis with adenotonsillitis.

BACTERIAL ADENOTONSILLITIS, LYMPHADENOPATHY, CELLULITIS, AND ABSCESS

Acute Bacterial Infection

Acute adenotonsillitis and lymphadenopathy due to bacterial causes are most often due to infection with group A streptococci. Bacterial infections of the head and neck may progress to cellulitis, nodal suppuration, or abscess formation. Cellulitis can be seen with adenotonsillitis and lymphadenopathy with or without abscess formation. The most common site of abscess or cellulitis/adenopathy is the peritonsillar space, followed by the retropharyngeal and submandibular spaces.[190] The most frequently cultured organisms in neck infections are *Streptococcus pyogenes, Staphylococcus aureus,* and *Bacteroides melanogenicus*.[190] Peritonsillar infections are associated with suppurative tonsillitis, with extension of infection and pus between the tonsillar capsule and the anterior and posterior tonsillar pillars. Retropharyngeal and parapharyngeal infections result from suppurative lymphadenitis associated with tonsillitis, pharyngitis, sinonasal infection, otitis media, dental infection, or trauma to the neck and oropharynx. Causes of submandibular infection include dental infection, salivary calculi, and skin infection. Bilateral cellulitis of the submandibular space is known as Ludwig's angina. Necrotizing cellulitis is a fulminant and extensive form of cellulitis that involves multiple fascial compartments. Necrotizing cellulitis is uncommon and may occur in children with a primary dermatologic process, such as chicken pox or infantile eczema, who then develop secondary infection with hemolytic streptococci.

The primary symptoms of infection include fever, sore throat, and a focal neck mass or diffuse swelling. Stridor or other symptoms of respiratory distress, odynophagia, dysphagia, and trismus indicate compromise of the upper aerodigestive tract. Local complications of neck infections include airway compromise, torticollis due to muscle spasm, and involvement of the vessels within the carotid sheath. The most common vascular complication is septic thrombophlebitis of the internal jugular vein.[191] Distant complications include infection of the mediastinum, lungs, and pleural and pericardial spaces.

The clinical presentation of peritonsillar abscess differs from that of retropharyngeal and submandibular space infections. There is typically unilateral enlargement and medial displacement of the tonsil with contralateral deviation of the uvula. A peritonsillar abscess may spread around or through the superior constrictor muscle and into the parapharyngeal space, leading to a parapharyngeal space abscess. By contrast, the clinical presentation of a retropharyngeal abscess (RPA) includes neck stiffness, torticollis, and posterior pharyngeal wall swelling that is often asymmetric.

Imaging helps differentiate between cellulitis, lymphade-

Copyright © 2003, Mosby, Inc. All rights reserved.

nitis, and abscess formation. Cross-sectional imaging is also used to assess the location and extent of abscess formation and to diagnose complications. It follows that imaging is seldom obtained for uncomplicated adenotonsillitis and may not be required for peritonsillar abscess, as the clinical presentation is often diagnostic. For those patients in whom imaging is indicated, contrast-enhanced CT is currently the examination of choice (Figs. 29-62 to 29-67). However, initial lateral plain neck films are sometimes obtained prior to cross-sectional imaging (Figs. 29-65A and 29-66A). Retropharyngeal space infection is accompanied by widening of the retropharyngeal soft tissues on films taken during inspiration, loss of cervical lordosis, and, occasionally, air in the retropharyngeal soft tissues (Fig. 29-66A).

CT is performed with 3 mm axial images obtained during the administration of an intravenous bolus of iodinated contrast medium. Images should be acquired from the skull base to the mediastinum. After immediate image review, it

VIEW IMAGE

may be useful to obtain limited delayed images through any area that is equivocal for abscess versus edematous lymphadenitis. Inflamed lymphoid tissue may enhance homogeneously or heterogeneously or may appear edematous, with decreased attenuation and mild delayed peripheral enhancement, nodal edema, or suppuration (Figs. 29-62 to 29-64). Abscess formation is also characterized by low attenuation and ring enhancement, particularly if the margins of the lesion no longer conform to the morphology of the node in which the inflammatory process originated (Figs. 29-65 to 29-67). Since a similar appearance can be seen with edematous lymph nodes, the demonstration of a focal area of low attenuation with rim enhancement is predictive but not entirely diagnostic of abscess formation.[192] Therefore, CT provides invaluable information in determining the need for surgical intervention, but it is not entirely accurate in the diagnosis of abscess formation. Ultrasound has been proposed as an effective modality for differentiating adenitis from abscess and for providing guidance for intraoperative aspiration and drainage.[193] Effacement of the left pyriform sinus and recurrent perithyroidal suppurative infections should suggest the diagnosis of an underlying pyrifiorm sinus fistula (Fig. 29-68). A CT diagnosis of cellulitis is made when there is

edema of the soft tissues and obliteration of fat planes without rim enhancement (Fig. 29-69). Necrotizing cellulitis is characterized by extensive stranding of the subcutaneous fat, low-attenuation phlegmonous change, and involvement of multiple fascial compartments (Fig. 29-70).

Airway encroachment by the inflammatory process should be noted and reported to the patient's physician and to any medical attendant accompanying the patient as soon as possible. Quite frequently there is displacement and a relative decrease in the caliber of the ipsilateral internal carotid artery in association with retropharyngeal infections. This phenomenon may be due to spasm and is generally asymptomatic.[194] Similarly, the ipsilateral internal jugular vein is often compressed by the inflammatory process (Fig. 29-64). Thrombophlebitis is a less common but potentially serious complication, as thrombus may propagate proximally, with potential hemorrhagic venous infarction of the brain.

Surgical incision and drainage is indicated in a child with imaging findings of a deep neck abscess.

Granulomatous Infection

Chronically enlarged lymph nodes can be a manifestation of granulomatous infections associated with organisms such as *Mycobacterium tuberculosis* (MTB), nontuberculous mycobacteria (NTM), and *Rochalimaea henselae* (cat scratch disease). These disorders differ in terms of clinical presentation, physical examination, and, to a lesser extent,

FIGURE 29-70 Streptococcal necrotizing cellulitis in a 2-year-old girl with a 6-day history of chicken pox and a 2-day history of rapidly progressive facial swelling. Contrast-enhanced CT shows massive swelling of the neck, diffuse stranding of the subcutaneous fat (*arrow*), low-attenuation phlegmonous change (*p*), and blurred muscle margins. The airway is narrowed.

imaging features.[195] Children with tuberculosis are usually systemically unwell. Children with NTM infection are usually aged between 2 and 5 years, are systemically well, and typically present with a unilateral nontender or minimally tender mass with overlying violaceous skin discoloration. Children with cat scratch disease usually have a history of a preexisting scratch from a cat.

Granulomatous adenopathy is occasionally massive enough to produce extrinsic airway compression. Involvement of retropharyngeal nodes can occasionally simulate a conventional bacterial abscess (Fig. 29-71).[196] On CT, involved lymph nodes typically have heterogeneous enhancement with foci of low attenuation and sometimes calcification. NTM infection is characterized by necrotic material extruding out of affected lymph nodes to involve the subcutaneous tissues and skin (Fig. 29-71).[196] Physical examination reveals associated violaceous skin discoloration. Inflammatory stranding of the soft tissues is not generally a feature of NTM infection but is usually seen with cat scratch disease.[196] It is important to differentiate granulomatous disorders from acute bacterial infection preoperatively, as surgical intervention, when indicated, should consist of excisional biopsy or curettage, as incision and drainage can lead to the formation of draining sinus tracts. Other causes of enlarged lymph nodes are described in Chapter 36.[197, 198]

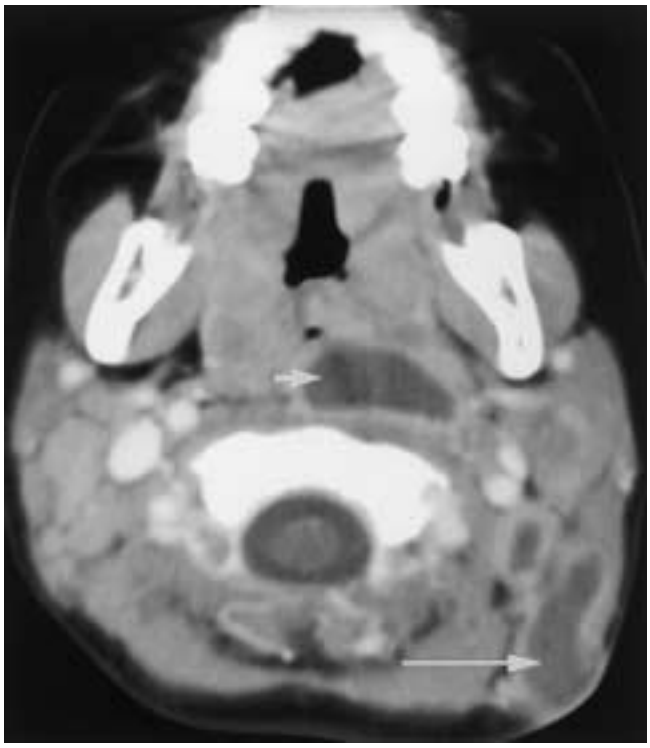

FIGURE 29-71 Nontuberculous mycobacterial infection in a 2½-year-old girl with a 4-week history of an enlarging left posterior triangle neck mass and deviation of the oropharynx to the right. Contrast-enhanced CT shows low-density, ring-enhancing spinal accessory adenopathy (*long arrow*), with extrusion of necrotic material involving the subcutaneous tissues and skin. Enlarged low-density, ring-enhancing left retropharyngeal adenopathy (*short arrow*) causes distortion and narrowing of the oropharynx (From Robson C.D. et al. Nontuberculous mycobacterial infection of the head and neck in immunocompetent children: CT and MR findings. AJNR 1999;20(10):1829–1835.)

SUPRAGLOTTITIS (EPIGLOTTITIS)

Supraglottitis, also known as *epiglottitis*, is an acute, potentially fulminating infection that occurs most commonly, though not exclusively, in children between 2 and 6 years of age. The infection is usually caused by *Haemophilus influenzae* type B. However, since the implementation of effective immunization against this organism, the incidence of epiglottitis has declined.[199] Previously immunized children with supraglottitis tend to be older and may have infection with other bacteria such as group A beta-hemolytic streptococci.[199] Invasive group A beta-hemolytic streptococcal infection with epiglottitis and necrotizing cellulitis has also been described as an unusual complication of varicella infection in children.[200]

Supraglottitis is characterized by an abrupt onset and a rapidly progressive course. Affected children present with drooling, fever, sore throat, dysphagia, restlessness, and inspiratory stridor with respiratory distress that may progress to complete airway obstruction. Bacterial supraglottitis must be clinically differentiated from other inflammatory causes of stridor such as viral laryngotracheobronchitis (croup) and bacterial tracheitis. As epiglottitis is considered to be a life-threatening condition, diagnosis and institution of appropriate therapy should be prompt. Every effort should be made to minimize patient manipulation, as this may exacerbate airway symptoms and provoke complete respiratory obstruction.

The diagnosis of supraglottitis can be based on clinical findings and endoscopic examination in the operating room. Physical examination reveals swelling and erythema of the epiglottis, aryepiglottic folds, false vocal cords, and arytenoids. However, if the diagnosis is uncertain and the patient's condition permits, a plain lateral radiograph of the neck can be obtained to help confirm the diagnosis and to exclude other causes of airway compromise. A physician should accompany the patient to the department, with equipment readily available for additional airway support. Ideally, radiographs should be obtained with the patient sitting comfortably in the erect position. The child should not be restrained or forced into a supine position, as this may exacerbate the respiratory obstruction. The typical plain film findings of supraglottitis include thickening of the free edge of the epiglottis, increased width of the aryepiglottic folds and arytenoids, and overdistention or ballooning of the hypopharynx (Figs. 29-72 and 29-73).[201]

FIGURE 29-73 Streptococcal supraglottitis in a 3-year-old boy with throat pain and drooling. The lateral plain film reveals thickening of the epiglottis and aryepiglottic folds (*arrowheads*). There is some overdistention of the hypopharynx.

VIEW IMAGE

FIGURE 29-72 Supraglottitis in a 17-year-old boy who complained of sore throat, dysphagia, and drooling. The lateral plain film reveals diffuse thickening of the supraglottic soft tissues (*arrow*) including the epiglottis (*e*). The diagnosis was confirmed endoscopically.

VIEW IMAGE

Other less common causes of epiglottic enlargement in the pediatric population include angioneurotic edema, epiglottic trauma, caustic laryngeal burns, abscess (Fig. 29-74), or hemorrhage within the epiglottis, radiation therapy, benign epiglottic lesions such as cysts or vascular malformations, or chronic epiglottitis, a rare persistent inflammatory process.[202, 203] The clinical presentation should aid in differentiating other lesions from acute bacterial supraglottitis. Treatment in children involves intravenous antibiotics and often nasotracheal intubation or tracheostomy.

LARYNGOTRACHEOBRONCHITIS (CROUP)

Laryngotracheobronchitis (LTB), or croup, is the most common inflammatory cause of stridor in young children. LTB may be spasmodic or follow an upper respiratory infection. Most infectious cases are viral in etiology and are usually attributable to the human parainfluenza viruses or, less commonly, to the influenza and respiratory syncytial viruses.[204] LTB is also a frequent and often severe complication of measles.[205]

VIEW IMAGE

FIGURE 29-74 Epiglottic abscess in an adolescent with severe sore throat. Axial contrast-enhanced CT shows a mass in the epiglottis (*arrow*), with partial airway obstruction. At surgery this was found to be an epiglottic abscess.

Mucosal edema has a significant effect in the subglottic larynx. The loosely attached mucosa at this level helps make this portion of the airway especially vulnerable to compromise. However, unlike epiglottitis, infectious LTB is generally a benign process that occurs primarily in younger children 1 to 3 years of age.[206] There is gradual onset of upper or lower respiratory tract symptoms, followed by the development of a classic barking, brassy cough and intermittent inspiratory stridor. Drooling and odynophagia are uncommon.

The radiographic appearance of LTB is variable, depending on the amount of edema and the phase of respiration during which the film is acquired. Plain films should be interpreted within the context of the clinical setting. The sensitivity and specificity of radiographs in croup have been reported to be low and may be more valuable in excluding other causes of airway obstruction such as a foreign body or bacterial epiglottitis.[207] Inspiratory plain films show ballooning and overdistention of the hypopharynx, with narrowing of the subglottic region and collapse of the cervical trachea.[208] During expiration, overdistention of the cervical trachea, probably secondary to laryngeal obstruction, may be seen.[209] The vocal cords and larynx appear poorly defined. On the AP examination the subglottic region is narrowed for 1 to 2 cm (the *steeple sign*), a finding that does not vary significantly between inspiration and expiration (Fig. 29-75).[209] The epiglottis and aryepiglottic folds are normal, which excludes epiglottitis.

LTB is managed with humidification, hydration, and, in some cases, corticosteroids and nebulized racemic epinephrine.[210] Intubation may be required for severe cases.

BACTERIAL TRACHEITIS

Bacterial tracheitis is an acute lower airway infection characterized by subglottic edema and purulent tracheal secretions and is usually due to infection with *S. aureus* or *H. influenzae*.[211] Widespread vaccination has nearly eradicated diphtheria, a common organism responsible for supraglottitis and laryngotracheitis in the early 1900s. Bacterial tracheitis is thought to arise as a secondary bacterial infection following viral LTB. The clinical course consists of a prodromal upper respiratory tract illness with stridor, fever, and variable respiratory distress.[211] Thick, purulent tracheal secretions, pseudomembranes, and ulcerated mucosa are characteristic endoscopic findings. Lateral plain films, although nonspecific, show narrowing and

irregularity of the subglottic airway (Fig. 29-76), usually with a normal epiglottis and aryepiglottic folds. Treatment consists of establishment of an airway, frequent tracheal suctioning, and appropriate antimicrobial therapy.

MISCELLANEOUS CONDITIONS

Hereditary angioneurotic edema, a rare autosomal dominant disease, is due to a deficiency of C1 esterase inhibitor. Lack of this inhibitor leads to vascular damage, and the child presents with recurrent urticaria, subcutaneous soft-tissue swelling, and airway obstruction secondary to edema of the epiglottis and aryepiglottic folds.[202] The clinical setting helps differentiate this cause of airway obstruction from acute epiglottitis.

Thickening of the epiglottis and aryepiglottic folds may occur following radiation therapy for head and neck neoplasms. The laryngeal structures are symmetrically thickened, with stranding of the paraglottic fat. Chronic stenosis of the airway may also occur (Fig. 29-77).

Wegener's granulomatosis is a necrotizing vasculitis that is characterized by inflammatory lesions, usually granulomas or areas of necrosis, in the respiratory tract and kidneys.

VIEW IMAGE

FIGURE 29-76 Staphylococcal laryngotracheitis in a 6-month-old boy who presented with fever and respiratory distress. VIEW IMAGE

Subglottic stenosis is a well-known manifestation of Wegener's granulomatosis in the pediatric population.[212] Tracheal stenosis causing stridor may also occur.[213] The differential diagnosis includes sarcoidosis, amyloidosis, and relapsing polychondritis, all uncommon pediatric lesions.[214]

SECTION SEVEN

TRAUMA

FACIAL TRAUMA

Direct trauma to the head and neck can affect the airway because of mass effect or distortion from hematoma, displaced bone fragments, and soft-tissue swelling. Clinical examination is the method of choice for establishing a diagnosis of nasal fracture or septal hematoma, although occasionally a nondisplaced fracture that is not palpable will be demonstrated radiographically. Fractures of the nose in younger children are poorly demonstrated due to the predominantly cartilaginous nasal framework and the presence of unfused nasal sutures.[215] Imaging, especially CT, may be useful for evaluating the complications of nasal trauma including nasal deformity and obstruction, secondary infection, septal hematoma (Fig. 29-78), and subsequent avascular necrosis of the nasal septal cartilage. In contrast to nasal fractures, imaging is helpful in the evaluation of acute

VIEW IMAGE

FIGURE 29-78 Nasal septal hematoma in a 2-year-old boy with facial trauma. Axial CT reveals the mixed-attenuation subacute nasal septal hematoma (*h*) obstructing the nasal airway.

nasoethmoidal and facial fractures. Axial 3 mm CT images should be obtained initially. Direct coronal images are obtained once the patient's cervical spine has been evaluated and spinal fracture or ligamentous instability has been excluded. Injuries to the nasoethmoidal, sphenoid, and frontal regions carry the additional risk of cerebrospinal fluid leak and posttraumatic meningoencephalocele. Mandibular fractures are often best assessed with panoramic radiographs and plain films.[216]

OROPHARYNGEAL TRAUMA

Penetrating oropharyngeal injury in children is common and is usually the result of impalement by a foreign object that was in the mouth at the time of a fall (e.g., lollipop or popsicle stick, toothbrush or pencil). The oropharyngeal injury ranges from a puncture wound with palatal or pharyngeal hematoma to a severe laceration. Complications of penetrating injuries include infection, subcutaneous emphysema, and vascular injuries with potential neurologic sequelae. The types of vascular injury include intimal dissection, transection, laceration, arteriovenous fistula formation, and pseudoaneurysm. Due to the proximity of the carotid artery to the lateral oropharynx, even apparently innocuous injuries can injure the vessel. Intimal dissection can lead to dissecting aneurysm or the formation of mural thrombus, with subsequent embolic cerebral infarction. Neither the mechanism of injury nor the degree of injury correlates with the potential for neurovascular sequelae, although there should be an increased index of suspicion with lateral oropharyngeal injuries.[217] In addition, neurovascular involvement may not become clinically apparent until days or weeks after the incident.

The radiographic evaluation and clinical management of penetrating oropharyngeal injury are controversial. Conventional angiography has been considered to be the examination of choice for the accurate diagnosis of arterial injuries if an abnormality is suspected clinically and immediate surgical intervention is not required.[218] An added benefit of the examination is the potential for endovascular intervention in selected cases. However, there are potential complications of conventional angiography, including stroke.

Cross-sectional imaging is useful for delineating the trajectory of the penetrating injury (Figs. 29-79 and 29-80) and provides objective evidence of proximity and actual injury to neck vessels (Fig. 29-81).[219] Penetrating injuries are often accompanied by extensive extraluminal air (Fig. 29-82). The sensitivity and specificity of helical CT are high for the detection of arterial occlusion, pseudoaneurysm, and arteriovenous fistula in teenagers and adults.[218] Helical CT images are rapidly obtained, and the modality is less invasive and less expensive than conventional angiography. However, the disadvantages compared with conventional angiography include the requirement of a higher volume of contrast agent, lower spatial resolution, potential degradation of image quality from imaging artifacts, and lack of immediate potential for endovascular intervention.[218]

MR angiography has been used to detect arterial injuries but not specifically penetrating or blunt trauma of the neck in children. The disadvantages of MR angiography include the need for patient monitoring and transport for the acutely ill patient, artifact caused by retained foreign body, and the presence of subcutaneous emphysema or air surrounding the great vessels.

LARYNGEAL AND TRACHEAL TRAUMA

The high position of the pediatric larynx, its mobility, and its flexibility make it less vulnerable or susceptible to blunt

nonpenetrating trauma than the adult larynx.[220] However, the submucosal tissues of the pediatric larynx are loosely attached to the underlying perichondrium, and there is a relative lack of fibrous tissue. These features predispose the pediatric larynx to massive soft-tissue swelling with edema or hemorrhage and significant functional consequences.[221] The mechanism of injury is often a direct blow to the child's extended neck, for example, against the dashboard of the car or against the handlebars of a bicycle. The laryngeal injury may not be recognized initially. Delayed recognition and treatment may result in chronic stenosis.

Acutely, the injury may result in contusion, hematoma, edema, or airway laceration. Additional injuries include arytenoid dislocation, recurrent laryngeal nerve injury (Fig. 29-83), true or false vocal cord avulsion, disruption of the thyroepiglottic ligament with posterior displacement of the epiglottis, and laryngotracheal separation.[221] Endoscopy and emergent tracheotomy are performed if complete or severe airway obstruction results. Endoscopic findings of laryngeal trauma include mucosal tears, hematomas, edema, immobile vocal cords, or cartilaginous fractures or dislocation, including cricoarytenoid disarticulation.[222] The endoscopic evaluation of partial airway obstruction, odynophagia, or hoarseness is limited when there is severe edema or blood in the endolaryngeal structures, and plain radiographs or CT may be requested. The advantage of CT in this setting is its ability to display the soft-tissue structures, and it is considered the definitive radiographic method for evaluating

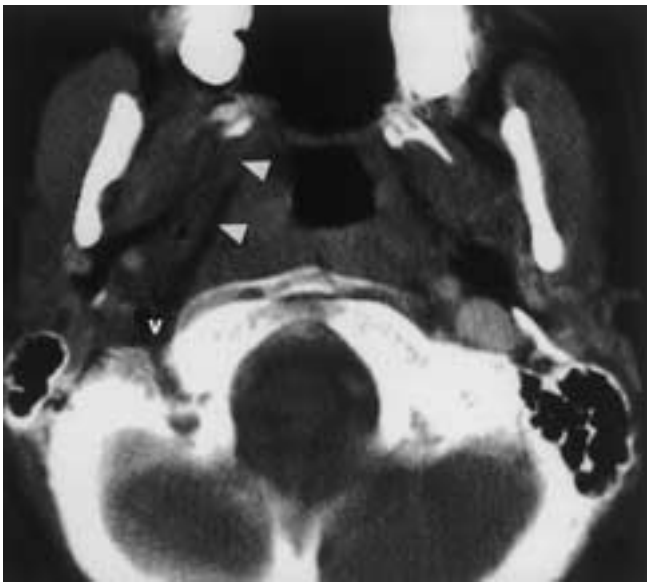

FIGURE 29-81 Popsicle-stick injury in a 7-year-old girl. Axial contrast-enhanced CT reveals the low-attenuation retained popsicle stick (*arrowheads*) within the soft tissues lateral to the pharynx, terminating in the expected location of the right internal jugular vein (*v*), which was thrombosed.

the injured larynx.[223] To best evaluate the noncalcified laryngeal cartilages in a child, delayed contrast-enhanced 1 to 3 mm helical axial images of the larynx should be obtained.

Edema, contusion, or laryngeal hematoma appears radiographically as swelling of the involved portion of the airway. Cervical or mediastinal emphysema suggests an

esophageal or laryngeal laceration or a laryngeal fracture (Fig 29-84). In the unusual instance that MR imaging is performed, edema of the injured laryngeal structure has a high T2-weighted signal intensity (Fig. 29-85). The degree and level of airway obstruction should be noted. Hyoid bone fracture can be detected on plain films and on CT. The epiglottis may be displaced posteriorly by edema or hematoma. Other cartilaginous fractures are difficult to detect in the noncalcified pediatric larynx, but they may be clinically suspected because of an abnormal thyroid eminence or an abnormal endoscopic airway contour.

Tracheal or laryngotracheal transection is a life-threatening injury and carries a high mortality. If the transection occurs at the thyrohyoid ligament, the supraglottic muscles pull the hyoid bone superiorly, and this can be seen on plain films.[224] Transection or avulsion of the recurrent laryngeal nerves is a complication of laryngotracheal transection, and vocal cord paralysis may be a chronic problem if the patient survives the initial injury.[225] Plain films or 2D coronal reformatted CT images show an increase in the craniocaudal extent of the larynx, as well as disruption of the tracheal air column.

Tracheal injuries or rupture from blunt trauma is not common but should be suspected with severe injury to the neck or chest.[226] Persistent pneumomediastinum or pneumothorax that is not relieved by a thoracotomy tube may be the only sign. Rupture of the anterior portion of the cervical trachea after severe coughing with the neck in extension has

been described as ''subcutaneous rupture'' and results in extensive cervical emphysema (Fig. 29-86).[226]

THERMAL TRAUMA AND CAUSTIC INGESTION

Laryngeal edema and obstruction can result from accidental inhalation of steam, hot particles such as ash, or scalding liquids.[226, 227] The supraglottis receives the brunt of exposure to thermal or caustic substances and is thus the most commonly injured region of the pediatric airway. Mild supraglottic edema resolves with conservative therapy and does not require imaging. Severe cases share similar clinical features with acute infectious epiglottitis and are best served by immediate endotracheal intubation or direct laryngoscopy, depending on the presence and severity of respiratory distress.[228] Caustic ingestion of acidic or basic substances may cause significant injury to the airway. The most severe injuries result from ingestion of large quantities of industrial-strength alkali or direct aspiration of caustic substances. Usually the degree of oral mucosal injury does not reflect the severity of the laryngeal burn.

Plain films in children with thermal trauma or caustic ingestion are nonspecific and may show thickening of the laryngeal structures simulating epiglottitis or croup (Fig. 29-87). In more severe cases, pharyngeal stenosis may occur because of scarring. If aspiration occurs, significant glottic, subglottic, and tracheal injury may result, with the potential for permanent subglottic or tracheal stenosis.

INTUBATION TRAUMA

Complications of intubation most commonly occur at the glottic or subglottic level. Acute injuries from intubation occur at predictable locations, including the medial surface of the arytenoids, the cricoarytenoid articulation, the posterior commissure, and the anterior surface of the cricoid lamina.[229] Acute changes, which may be visualized endoscopically, include edema and hyperemia, mucosal erosion, and ulceration. Granulation tissue, intubation granulomas, glottic webs, submucosal cysts, and vocal cord immobility may eventually develop. Traumatic intubation may also dislocate one of the arytenoids or may fracture the cricoid. Endotracheal intubation is the most common cause of acquired subglottic stenosis.[230] However, there are other important etiologic risk factors, including gastroesophageal reflux, sepsis, low birth weight, and frequent self-extubations; the exact role of each of these risk factors is unknown.[231]

Stridor or hoarseness after extubation suggests a complication of intubation. Although imaging may be used to help localize the problem, endoscopy is the mainstay of diagnosis.

An intubation granulation may be focal or nodular, and it occurs most commonly at the vocal process of the arytenoid.[229] Airway fluoroscopy shows a focal mass projecting into the airway at the glottic level. Ischemic pressure necrosis from an endotracheal tube may result in posterior wall granulation tissue, which may lead to glottic stenosis. On imaging this will appear as airway narrowing at the glottic level.

Subglottic cysts are rare acquired retention cysts that usu-

ally follow long-term intubation in neonates (Fig. 29-88). The mechanism of formation is fibrosis and obstruction of the mucous glands with subsequent cyst formation.[232] Asymmetric subglottic narrowing may be seen on AP plain films and can mimic a subglottic hemangioma.[232]

The severity or extent of acquired subglottic stenosis may be determined on plain films or fluoroscopy of the airway. CT and MR imaging are usually not performed to evaluate intubation-related complications. Imaging is important, however, when there is complete or severe laryngeal stenosis and it is difficult to determine endoscopically the length of the stenosis. Helical CT with 2D coronal reformatted images and direct coronal MR imaging are helpful in evaluating severe grades of laryngotracheal stenosis and demonstrate the length of stenosis. The cross-sectional area of the airway can also be determined using either CT or MR imaging (Fig. 29-89). In this clinical setting, intravenous contrast is not required.

A tracheotomy often results in similar acquired lesions in the airway, including stomal and distal tracheal granulomas, subglottic stenosis, and collapse of the anterior tracheal wall.[233] The radiographic appearance of these lesions is similar to that of postintubation lesions (Fig. 29-90).

INGESTED OR ASPIRATED FOREIGN BODY

The majority of foreign bodies that are ingested pass undetected into the stool. Occasionally foreign bodies become impacted within the aerodigestive tract. The clinical presentation of foreign bodies lodged in the pharynx depends on the age of the patient and the site and morphology of the object. Older patients generally volunteer a history and complain of symptoms such as a pricking pain sensation, odynophagia, and a lump in the throat. Younger patients may simply refuse to eat, and blood-stained saliva may be observed.[234] Fish bones and radiolucent foreign bodies are associated with an increased risk of complications in patients under the age of 10 years.[235] Ingested sharp bones, which tend to lodge in the oropharynx or tonsils, can penetrate the mucosa and provoke local inflammatory complications such as retropharyngeal abscess. Foreign objects that are lodged in the oropharynx are amenable to direct inspection and removal with the aid of a tongue depressor or laryngoscope.[234] Other objects can be removed via transnasal flexible endoscopy. Plain films should be

Endoscopy showed a benign subglottic cyst.

reserved for patients in whom pain indicates obstruction below the level of the cricoid and for children with persistent symptoms despite a negative physical examination.[234] Contrast-enhanced CT should be performed if local complications such as abscess formation are suspected at the time of presentation or following removal of the foreign body.

Laryngotracheal inhaled foreign bodies are less common than bronchial foreign bodies, accounting for fewer than 20% of all aspirations.[236] However, because of the potential for complete airway obstruction, laryngotracheal foreign bodies are more hazardous than those lodged in a bronchus. The clinical presentation is generally obvious with severe airway obstruction and stridor.

Plain films of the neck detect foreign bodies that are radiopaque and help exclude croup, although subglottic edema and swelling may be seen with laryngotracheal foreign bodies.[237] Coins, pen caps, screws, pins including open safety pins, and small toy objects are common radiopaque foreign bodies that may lodge in the larynx,

trachea, or bronchi (Fig. 29-91). However, a significant proportion of foreign bodies, especially food particles such as peanuts or small vegetable matter, may not be seen, even with magnification views.[237] In this situation, indirect signs of aspiration such as subglottic swelling or airway narrowing should be reported.[238] Both AP and lateral neck films should be obtained to localize the object to the larynx or the esophagus and to determine the contour of the foreign body.

Unlike foreign bodies lodged within the upper airway, bronchial foreign bodies may present more insidiously. Smaller objects and particulate matter usually lodge in the distal bronchi. If the symptoms are mild, diagnosis may be delayed by weeks to months. As the aspiration is often not witnessed and physical findings are subtle, radiographs are an important part of the patient's evaluation.

In most cases, radiographic diagnosis is based upon changes secondary to unilateral obstruction of the airway. Partial occlusion of the bronchus produces a ball-valve effect with distal air trapping. This results in unilateral emphysema, mediastinal shift, and a decrease in pulmonary blood flow to the affected side. In the uncooperative child, lateral decubitus views usually suffice. Bronchial foreign bodies that have been present for longer periods may cause chronic inflammation in the bronchial lumen and complete bronchial obstruction, resulting in atelectasis, infiltrates, or effusions. However, in this situation it is also possible to have minimal radiographic findings. For instance, bilateral bronchial foreign bodies may not result in mediastinal shift or signs of air trapping. Endoscopy should be performed whenever clinical suspicion is high.

VIEW IMAGE

VIEW IMAGE

FIGURE 29-92 Esophageal foreign body, with perforation and abscess formation, in a young child who presented with respiratory distress. Lateral film from a barium swallow examination shows marked prevertebral soft-tissue swelling. A collection of barium is seen extending five vertebral bodies in length, which was caused by posterior esophageal wall perforation by a foreign body. The edema and the collection caused a mass effect on the airway, resulting in the presenting symptoms of airway compromise.

An esophageal foreign body may also present with airway obstruction secondary to direct pressure on the posterior larynx or trachea.[239] Impaction most commonly occurs at or just below the level of the cricopharyngeus muscle.[240] If the foreign body ulcerates and perforates the esophagus, the edema and inflammatory response may compromise the airway. Plain films are important for evaluating esophageal foreign bodies because most are coins. A barium swallow usually is performed to show the site of perforation and extravasation, and if perforation is likely, this study should be performed with water-soluble nonionic contrast (Fig. 29-92).[207] An esophageal stricture following a surgical repair for a congenital lesion such as esophageal atresia predisposes to obstruction by an esophageal foreign body.[201] A barium swallow helps delineate the location and extent of the stricture.

MISCELLANEOUS CONDITIONS

Nasopharyngeal stenosis, a rare cause of airway compromise, usually results from scarring after tonsillectomy and adenoidectomy, especially when surgery involved aggres-

sive circumferential cauterization of the nasopharyngeal tissues. Before the widespread availability of antibiotics, nasopharyngeal stenosis was a complication of syphilis or tuberculosis of the pharynx. Fusion of the soft palate and tonsillar pillar to the posterior pharyngeal wall causes complete or partial obstruction. Patients present with respiratory distress and nasal obstruction weeks to months after surgery. The diagnosis is usually made by the clinical history and endoscopy. Plain films may demonstrate narrowing or complete nasopharyngeal obstruction. Treatment involves pharyngoplasty with laterally based pharyngeal flaps.[201]

SECTION EIGHT

BENIGN TUMORS AND TUMOR-LIKE CONDITIONS

ADENOIDAL AND TONSILLAR HYPERTROPHY

Hypertrophy of the adenoids and palatine tonsils is common in the pediatric population. Adenoidal enlargement produces chronic nasal and nasopharyngeal obstruction and sometimes impairment of the ability to smell.[241] Clinical symptoms include a ''mouth-open'' posture, mouth breathing, hyponasal speech, and nocturnal snoring. Airway compromise or dysphagia caused by palatine tonsillar hypertrophy in the child is also common.[242] Less commonly, lingual tonsillar hypertrophy may be associated with airway obstruction.[243] Symptoms of airway obstruction from enlarged tonsils include obstructive sleep apnea and/or snoring, restless sleep, irritability, or decreased alertness.[244]

Although various measurements and ratios have been described to determine the normal adenoidal size, correlation of preoperative radiographic adenoidal size with surgical observations and specimens varies from excellent to poor.[245, 246] A lateral radiograph should be obtained during inspiration through the nose, with the mouth closed. The adenoid to nasopharyngeal (AN) ratio may aid in diagnosing prominent, clinically significant adenoids (Fig. 29-93).[247] Using this method, adenoidal hypertrophy can be reliably diagnosed in a symptomatic patient when the AN ratio is 0.8 or greater (Fig. 29-94).[247] Obstructive symptoms are not generally seen in patients with an AN ratio less than 0.5.[15] Because tremendous variation in adenoidal size exists in the normal pediatric patient, any measurement should be used with caution and clinical symptoms must always be considered. In assessing for obstruction, the airway anterior (between the anterior border of the adenoids and the posterior border of the maxillary antra) and inferior to the adenoids (from the inferior border of the adenoids to the superior border of the soft palate) should be assessed.[241] In certain craniofacial syndromes such as trisomy 21, because of the smaller nasopharyngeal size, a lower AN ratio may be clinically significant.[242] The presence of small mucous retention cysts within the adenoids is not uncommon and should not be mistaken for tumor (Fig. 29-95).

Palatine tonsillar hypertrophy appears as smooth, rounded, or oval soft-tissue masses on either side of the oropharynx, bulging into the pharyngeal column (Fig. 29-12). Sagittal MR images, obtained just off the midline, show similar findings, with the fullness in the tonsillar fossa being isointense to pharyngeal musculature on T1-weighted images and hyperintense to muscle on T2-weighted images (Fig. 29-14). On CT, palatine tonsillar tissue is isodense to the surrounding musculature. On MR imaging and CT, hypertrophic lingual tonsils are similar in appearance to palatine tonsils, but they occur at the tongue base, often filling the vallecula (Fig. 29-13).

The main indications for adenoidectomy, tonsillectomy, or adenotonsillectomy in childhood are recurrent infection and obstructive tonsillar and/or adenoidal enlargement.[244, 248] Infections include febrile tonsillitis (more than three episodes per year), peritonsillar abscess, and persistent or recurrent otitis media.

RECURRENT RESPIRATORY PAPILLOMATOSIS

Recurrent respiratory papillomatosis (RRP) is the most common benign neoplasm of the larynx in children and the second most frequent cause of childhood hoarseness.[249] The disease is caused by the human papilloma virus (HPV).[250, 251] RRP in children has been linked to maternal genital HPV infections, and vertical transmission of the virus has been observed.[252] However, few children exposed to genital warts at birth develop clinical symptoms.[253] RRP is generally diagnosed between 2 and 4 years of age.[251] Although the course of the disease is variable, there is a tendency for recurrence and for dissemination of lesions throughout the respiratory tract. Although spontaneous

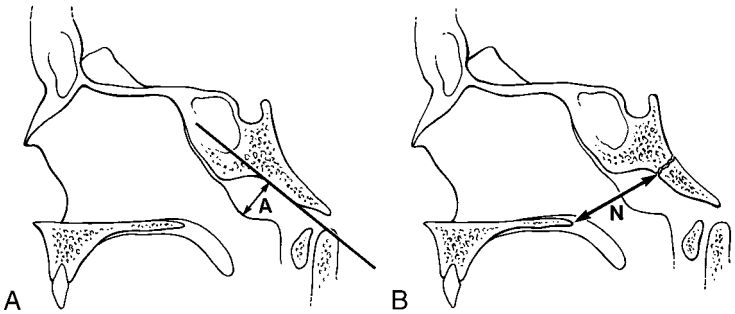

FIGURE 29-93 The AN ratio may be helpful in determining adenoidal size on the lateral radiograph. In the symptomatic child (with obstructive sleep apnea or recurrent otitis media), a ratio greater than 0.8 is considered abnormal. **A**, Adenoidal measurement. The distance (*A*) between the maximum convexity of the adenoids and a line drawn along the basiocciput is measured. **B**, Nasopharyngeal measurement. The distance (*N*) between the posterior hard palate and the sphenooccipital synchondrosis is determined. (From Fujioka M et al. Radiographic evaluation of adenoidal size in children: adenoidal-nasopharyngeal ratio. AJR 1979;133:401–404.)

remission has been documented, childhood-onset RRP is more aggressive than its adult counterpart.[254] The papilloma lesions may be pedunculated or sessile and often occur in irregular exophytic clusters. Squamous cell carcinoma occasionally arises in RRP in the absence of known risk factors such as radiation therapy and smoking.[255, 256]

The classic symptoms of RRP are progressive hoarseness, stridor, and respiratory distress.[254] Because growth of the papillomas is gradual, acute airway obstruction is rare. Papillomas are often multiple and most commonly occur at the glottic level, but they can be found virtually anywhere in the aerodigestive tract.[257] Recurrent disease is often subglottic.[258] The preoperative diagnosis of RRP is best made with flexible fiberoptic endoscopy. Plain films show small, pedunculated nodular masses within the airway (Fig. 29-96). CT and MR imaging may show small nodules adherent to the airway wall and projecting into the lumen. Larger recurrent lesions may have transbronchial spread, with formation of lung masses and cavities.

No single treatment appears to be consistently effective in the eradication of RRP. The goal of therapy is complete surgical removal of papillomas with preservation of normal structures. The CO_2 laser has been the instrument most commonly used for surgical treatment. Recently, endoscopic microdebriders have also been used to debulk larger lesions and may cause less laryngeal scarring than CO_2 lasers.[254] Many adjuvant therapies have been evaluated, including antiviral and chemotherapeutic agents. The most commonly recommended adjuvant therapy is interferon.[259]

JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

Juvenile nasopharyngeal angiofibroma (JNA) is a benign but aggressive vascular tumor found almost exclusively in adolescent males. Unilateral nasal obstruction and recurrent spontaneous epistaxis are the most common presenting symptoms.[260] JNA usually arises at the sphenopalatine foramen on the lateral nasopharyngeal wall. The tumor is locally destructive and spreads over time to involve contiguous structures: laterally the pterygopalatine and pterygomaxillary fissures and the infratemporal fossa; anteriorly the nasal fossa and maxillary antrum; and superiorly the ethmoid air cells, sphenoid sinus, orbit, cavernous sinus, and middle cranial fossa. Intracranial extension usually occurs via the superior orbital fissure. Although JNA is benign, it is extremely vascular, being primarily supplied by the ipsilateral internal maxillary artery, the ascending pharyngeal artery, and the palatine arteries. It also may recruit a vascular supply from the

sphenoidal and ophthalmic branches of the internal carotid artery.[260]

The classic plain film findings include an ipsilateral nasal cavity and nasopharyngeal mass, widening of the pterygopalatine fossa, anterior displacement of the posterior wall of the maxillary sinus, erosion of the medial pterygoid plate, and extension of tumor to the sphenoid sinus. Axial and coronal CT images (3 mm slice thickness) are used to delineate bony erosion. Central skull base foramina and fissures that may be enlarged and/or eroded by pressure effects from the tumor include the sphenopalatine foramen, the foramen rotundum, the vidian canal, and the inferior and superior orbital fissures. On contrast-enhanced images there is immediate and intense tumor enhancement. On MR imaging the mass is generally heterogeneous, with prominent vascular flow voids (Fig. 29-97). One advantage of MR imaging over CT is the increased ability to differentiate obstructed secretions from intrasinus tumor. Conventional angiography shows the prominent vascular supply, usually from the ipsilateral external carotid artery branches but often involving the contralateral vessels as well. An internal carotid artery supply may be seen when the lesion has extended intracranially. A dense homogeneous blush persisting into the venous phase is typical.[261] Early draining veins are not common.

Treatment consists of surgical resection, often with preoperative embolization.[261] For patients with tumor involving the nasopharynx, nasal cavity, paranasal sinuses, and pterygopalatine fossa, the transnasal endoscopic technique offers minimally invasive resection of the entire tumor mass with minimal morphologic disturbance.[262] Radiation is not the primary treatment, but it may be considered in some cases.[263]

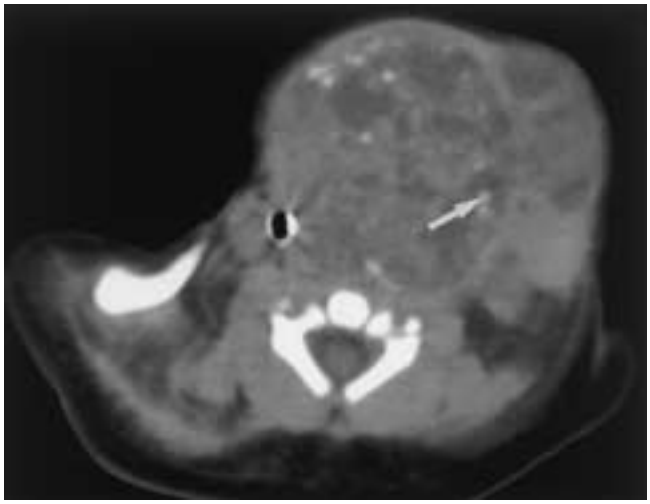
The mass is isointense with gray matter. The diagnosis was confirmed by biopsy.

MISCELLANEOUS CONDITIONS

Antrochoanal polyps and inflammatory sinonasal polyps, especially in children with cystic fibrosis, may cause nasal airway obstruction. Imaging findings are similar to those described in adults (Figs. 29-98 and 29-99).

Fibroosseous lesions such as fibrous dysplasia can also obstruct the airway due to involvement of facial bones and nasal turbinates (Fig. 29-100).

Teratomas are the most common congenital tumors. The head and neck region is the second most common location for teratomas in early infancy. Approximately 75% of childhood head and neck teratomas are diagnosed during the first year of life, and those involving the neck are usually noted at birth.[264] Antenatal diagnosis of teratoma can be made with sonography or MR imaging (Fig. 29-101). The postnatal clinical presentation of teratoma involving the neck is a large mass that causes respiratory difficulty and/or feeding problems. On CT teratomas appear heterogeneous but sharply circumscribed, with solid and cystic areas and variegated enhancement of the solid component. Hypodense areas indicating fat and/or hyperdense calcific foci are helpful in suggesting the preoperative diagnosis of teratoma and in differentiating the tumor from lymphatic malformation (Fig. 29-102).



VIEW IMAGE

FIGURE 29-102 Teratoma in a 1-day-old boy, one of triplets, born with a large neck mass. The baby was intubated at birth. Axial nonenhanced CT demonstrates a heterogeneous solid and cystic tumor containing punctate calcifications (*arrow*). The endotracheal tube indicates the position of the displaced trachea.

Hamartomas are uncommon developmental masses that can produce airway obstruction. A neuroglial or hypothalamic hamartoma can occasionally extend through a skull base defect to present as a nasopharyngeal mass (Fig. 29-103).

Large neurofibromas and plexiform neurofibromas sometimes cause airway obstruction (Fig. 29-104). Neurofibroma is typically well circumscribed, with bone remodeling rather than frank bone destruction. Plexiform neurofibroma appears as a lobulated or poorly defined heterogeneous mass involving multiple fascial compartments. A characteristic cross-sectional imaging appearance is the *target sign*.[265] This refers to punctate central high attenuation and peripheral low attenuation within multiple tumor nodules on CT.

The larynx is the most common site for isolated amyloid, a rare benign condition in children.[266] On CT the solid laryngeal mass is similar in attenuation to muscle, and on MR imaging the signal intensities of the amyloid disease are isointense with muscle. The process enhances with gadolinium.[266]

VIEW IMAGE

FIGURE 29-104 Supraglottic neurofibroma in a 2-year-old girl with neurofibromatosis type 1. **A**, Axial contrast-enhanced CT reveals an obstructing supraglottic mass (*arrows*). Since the image was acquired during the administration of contrast, enhancement of the tumor has not yet occurred. **B**, Sagittal contrast-enhanced T1-weighted MR image demonstrates the enhancing tumor extending between the epiglottis and the glottis. The patient has a tracheostomy tube in place.

Congenital hypothyroidism may be caused by dyshormonogenesis, resulting in a large thyroid gland that is in the normal thyroid bed.[267] The mass may be extensive and may result in airway compromise (Fig. 29-105).[268]

VIEW IMAGE

FIGURE 29-105 One-year-old child with congenital hypothyroidism and stridor. Axial contrast-enhanced CT shows symmetric enlargement of the thyroid gland. Note that the gland does not enhance normally. The common carotid arteries (*A*) and internal jugular veins (*V*) are deviated posterolaterally, and the trachea is compressed.

SECTION NINE

MALIGNANT TUMORS

Lymphoma is the most common malignant tumor of the head and neck. Sarcomas, specifically rhabdomyosarcomas, are the next most common tumors. Thyroid carcinoma and salivary gland malignancies are the most common tumors of glandular origin. The most common epithelial malignancy is nasopharyngeal carcinoma.[269, 270]

LYMPHOMA

Lymphoma is classified as Hodgkin's disease or non-Hodgkin's lymphoma. Both types of lymphoma display a male predilection. Hodgkin's disease (HD) is the most common type of lymphoma to involve the head and neck and is most common in adolescence. In children HD is primarily nodal, and at initial presentation, extranodal disease is rare.[269] During childhood, airway obstruction is not a common presenting symptom of HD. The presence of the Reed-Sternberg cell, a multinucleate giant cell, differentiates HD from other types of lymphoma.

Non-Hodgkin's lymphoma (NHL) primarily affects children between 2 and 12 years of age. It is classified as

Copyright © 2003, Mosby, Inc. All rights reserved.

U-cell (or undefined cell proliferations without specific markers), B-cell, T-cell, histiocytic, and unclassifiable types (technically insufficient for specific cytologic classification).[271] In children, although cervical adenopathy may be the presenting sign of disease, extranodal involvement is common, especially the lymphoid tissues of Waldeyer's ring.[269] When disease involves the airway, symptoms of airway obstruction occur. NHL occurs more frequently in patients with acquired or congenital immune disorders such as Wiskott-Aldrich syndrome and acquired immune deficiency syndrome (AIDS).[272–274] High grade B-cell lymphomas that arise in immunosuppressed transplant patients and those with AIDS occur in association with EBV infection.[273, 275] The posttransplantation lymphoproliferative disorders (PTLD) are typically associated with EBV infection and encompass a variety of disorders ranging from reversible polyclonal lymphoid hyperplasia to frankly malignant high-grade monoclonal lymphoma.

Burkitt lymphoma is a B-cell NHL with unique epidemiology. The disease occurs both as an endemic African form and as a nonendemic American form.[270] Antibody titers to EBV are high in the African type, but only 15% to 20% of American children have elevated viral titers.[276, 277] The African type commonly involves the oral cavity and jaw, and the American type more commonly presents as an abdominal mass. Involvement of the cervical lymph nodes, nasopharynx, and oropharynx is less common than in the other lymphomas.[278] However, Burkitt's lymphoma has an extremely short doubling time and is the fastest-growing human tumor. As a result, it may present with rapidly progressive airway obstruction.[276, 277]

CT and MR imaging cannot differentiate nodal disease caused by HL from that of NHL. Lymphadenopathy, sometimes only 1 cm in diameter, is seen in multiple locations, usually with a dominant larger node or group of nodes. However, because prominent hyperplastic nonneoplastic lymphadenopathy is common in the pediatric population, it may be impossible to differentiate lymphomatous from reactive nodes. Lymphomatous adenopathy is not commonly necrotic or calcified, although focal calcifications may be seen in treated nodes. Nodal biopsy is required to establish the diagnosis and the disease subtype.

NHL involving Waldeyer's ring is usually bilateral and fills or obliterates the airway. On CT the tumor is isodense to the pharyngeal musculature, and on MR imaging the tumor is isointense to muscle on T1-weighted images and generally hyperintense to muscle on T2-weighted images (Fig. 29-106). In children, extranodal lymphoma is nonspecific in appearance, but because lymphoma is one of the most common lesions in the head and neck, it should be included in the differential diagnosis of any large neck mass with malignant characteristics on CT or MR imaging (Fig. 29-107). Enlargement of lymphoid tissue in transplant recipients should raise the possibility of PTLD (Fig. 29-108).

Because of improved detection and staging and multimodality treatment regimens, the 5-year survival rate for lymphoma has improved over the past two decades. On follow-up CT or MR imaging after successful treatment, extranodal disease should appear smaller, or it should completely resolve. Lymphomatous nodes should decrease in size and number, although small nodes may remain. A new nodal or nonnodal mass following treatment for childhood lymphoma may represent recurrent disease or a new primary tumor because these patients are at risk for secondary malignant disease.[279]

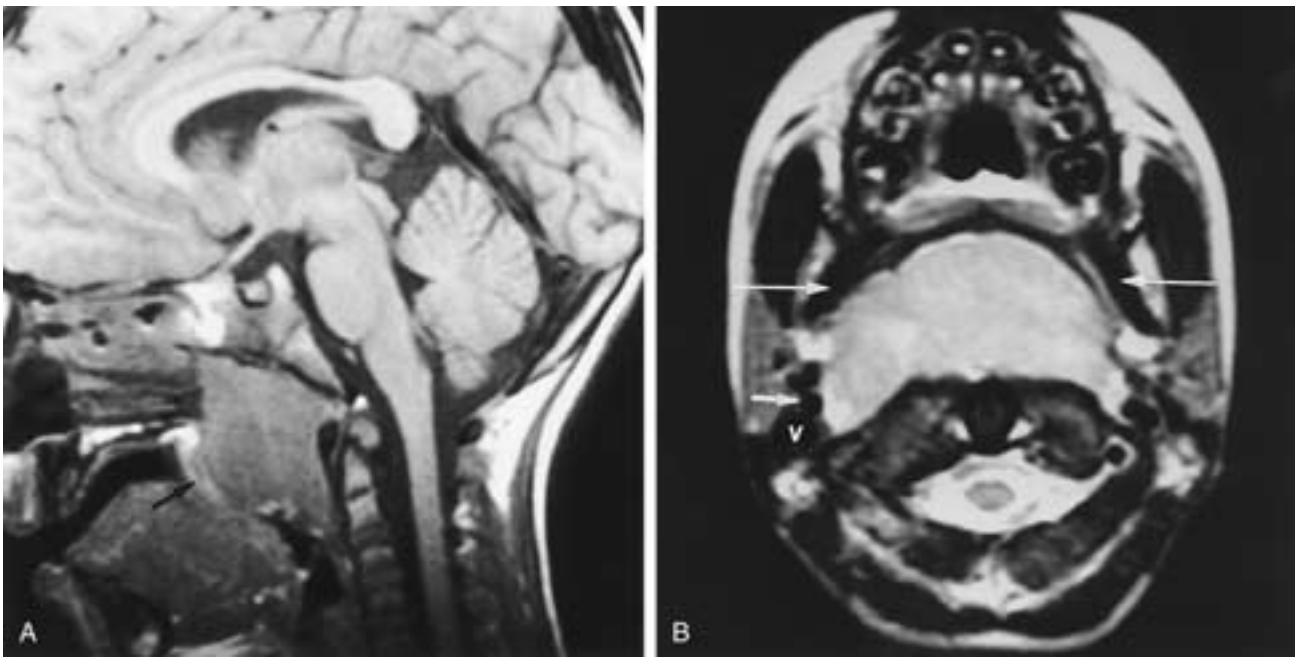

FIGURE 29-106 NHL in a 6-year-old boy with severe airway obstruction. **A**, T1-weighted sagittal image shows a large nasooropharyngeal mass obliterating the airway. The soft palate (*arrow*) is pushed anteroinferiorly by the mass. **B**, On this FSE T2-weighted axial image, the mass has pushed the vessels (*arrow*, internal carotid artery; *v*, internal jugular vein) and the pterygoid muscles (*long arrow*) laterally. Despite the large size, there is no skull base destruction and no cervical adenopathy.

RHABDOMYOSARCOMA

Rhabomyosarcoma (RMS) is a malignant tumor of mesenchymal origin thought to arise from cells committed to a skeletal muscle lineage.[280] In the pediatric population, RMS is the most common soft-tissue sarcoma and the second most frequent head and neck malignancy.[281] The disease has a peak age presentation at 2 to 5 years and again at 15 to 19 years, and there is a slight male predominance.[282] Although most cases of RMS appear to be sporadic, some young children (aged < 3 years) have identifiable constitutional mutations of the *p53* tumor suppressor gene and a possible hereditary predisposition to cancer.[283] RMS has been associated with familial syndromes such as neurofibromatosis type 1.[284] There is also an association between bilateral or hereditary retinoblastoma of the orbit and RMS.[285]

Three main histopathologic types of rhabdomyosarcoma have been described: (1) embryonal, which accounts for 75% of tumors and is most common in younger children; (2) alveolar (20%), which has the worst prognosis and is seen in older children; and (3) pleomorphic, which accounts for 5% of the cases. The embryonal and alveolar subtypes of RMS have been found to have distinct genetic alterations that may play a role in the pathogenesis of these tumors.[280] Head and neck disease is further divided into three categories based on the site of occurrence: (1) orbital, which carries the best prognosis; (2) parameningeal, which has the poorest prognosis; and (3) other sites. Parameningeal disease arises from tumors in locations such as the middle ear space, posterior nasopharynx, nasal cavity, paranasal sinuses, and masticator space. Tumors erode directly through bone or extend through skull base foramina via perineural spread to produce an epidural mass and sometimes meningeal involvement. The incidence of metastatic cervical adenopathy at the time of presentation ranges from 3% to 25%.[282, 286] As with other head and neck malignancies in children, presenting signs and symptoms may initially be innocuous, resulting in a delay in diagnosis. Large nasopharyngeal, oropharyngeal, or laryngeal lesions may present with airway obstruction (Figs. 29-109 and 29-110). The prognosis, as reported by the Intergroup Rhabdomyosarcoma Study (IRS), is best with complete surgical resection.

Imaging shows a soft-tissue mass, often with bony tive, but bony remodeling can also be seen. The tumor is usually heterogeneous, may be hemorrhagic or necrotic, and has relatively well-circumscribed borders. The tumors enhance following the administration of contrast for CT or MR imaging. For baseline imaging, both CT and MR imaging should be performed. Axial and coronal CT images are used for assessment of bony destruction (Fig. 29-109A). The coronal images should be 3 mm thick, and the skull base should be carefully evaluated for erosion or widening of cranial nerve foramina. Multiplanar MR images should include T2-weighted or fast spin-echo inversion recovery pulse sequences and gadolinium-enhanced, fat-suppressed, T1-weighted images (Figs. 29-109B and 29-110). The signal intensity of tumors on the T2-weighted images is variable. Coronal contrast-enhanced, T1-weighted images are very useful for the detection of epidural masses and meningeal enhancement that indicate the presence of parameningeal disease (Fig. 29-109B). It is important to detect this preoperatively because combined craniofacial surgery may then be required.[281] A survey of the cervical lymph node

chain also should be performed to detect metastatic adenopathy. The diagnosis is confirmed by biopsy.

Treatment involves surgery, radiation therapy, and chemotherapy. Posttreatment resolution of the tumor is a good indicator of the prognosis, but disease may recur at a later date, and serial scans are usually obtained to detect early disease recurrence.

NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma, previously called lymphoepithelioma, is an uncommon malignancy in children. However, this tumor is the most common pediatric epithelial carcinoma and has the highest incidence in parts of Asia and Africa.[287] Nasopharyngeal carcinoma may be similar in presentation, imaging appearance, and even histology to the more common tumors, lymphoma and rhabdomyosarcoma.[270] As in the adult population with this disease, children commonly have elevated titers of EBV, suggesting an infectious etiology.[270] Unilateral nasal obstruction and otitis media, epistaxis, and rhinorrhea are common presenting findings.[269] Headache and cranial neuropathy imply skull base and intracranial extension. Most children have metastatic cervical adenopathy at the time of presentation.[270]

CT and MR imaging of nasopharyngeal carcinoma show a large, inhomogeneous mass filling the nasopharyngeal airway, often with skull base erosion and intracranial extension. Necrotic cervical adenopathy, particularly involving the retropharyngeal and high jugular chain nodes, is common.

A combination of radiotherapy and systemic chemotherapy is used for optimal disease-free survival.[287]

MISCELLANEOUS CONDITIONS

There are a variety of miscellaneous rare malignancies in the head and neck, which may have airway involvement. Neuroblastoma of the head and neck is most commonly metastatic from neural crest sympathetic precursor cells in the adrenal gland. There usually is disease in the cervical lymph nodes, the orbit, or the skull.[270] CT or MR imaging of the tumor is nonspecific, showing either a large cervical node or a mass in the orbit or skull, sometimes with dystrophic calcification and often with extensive bone destruction. Imaging of the primary lesion, especially the adrenal gland, should be performed.[270]

Malignant rhabdoid tumor is a rare aggressive pediatric neoplasm that originates either from the kidney or from extrarenal sites, including the head and neck.[288] The radiographic appearance is nonspecific (Fig. 29-111).

Thyroid carcinoma is rare in children and is strongly associated with a prior history of irradiation.[270] This tumor also may be increased in incidence in long-term survivors of acute lymphoblastic leukemia.[289] Patients present with a palpable neck mass, hoarseness, or dysphagia.[289] Ultrasound or an ^{123}I thyroid scan is often used to image the lesion and determine if the mass is ''cold.'' Cold nodules in children have a higher incidence of malignancy, up to 29% in some series, than in adults.[290] The definitive diagnosis is made by fine needle aspiration or surgical biopsy.

Laryngeal carcinoma, also a rare pediatric neoplasm, is

usually associated with RRP and is similar in CT and MR appearance to adult laryngeal carcinoma.[255, 291]

Synovial sarcomas may occasionally occur in proximity to the airway and produce airway symptoms (Fig. 29-112). Chondrosarcomas, other sarcomas, malignant teratomas, and other carcinomas have been reported in the head and neck in children, but they rarely cause airway compromise. Skull base lesions, when large, may affect the airway.

Airway neoplasms in children with AIDS include NHL, bronchial leiomyomas, a benign smooth muscle tumor, and bronchial leiomyosarcomas.[270] However, inflammatory diseases such as chronic sinusitis and otitis media are more common in pediatric AIDs patients.

INTRODUCTION

Although entirely within the soft tissues of the neck, the mucosal surfaces of the larynx are readily accessible to either indirect visualization using a mirror or direct visualization by employing an office endoscope. After the scope is passed through the nose and directed toward the larynx, almost all of the endolarynx can be seen and most tumors are diagnosed at the initial office visit. If voice problems are suspected, videotaping of the direct examina-

Copyright © 2003, Mosby, Inc. All rights reserved.

tion allows assessment of subtle movement disorders. Only if the initial clinical evaluation is inconclusive is a direct examination under anesthesia performed. This inspection allows better direct observation of the laryngeal mucosa, as well as the best direct examination of the laryngeal ventricle and the subglottic region. Biopsies can be performed to confirm a suspected diagnosis and to document subtle mucosal extension not appreciated on the office endoscopic examination. What cannot be visualized is deep soft-tissue extension or cartilaginous involvement. That evaluation falls into the domain of imaging, done as an adjunct to direct evaluation.

The larynx presents one of the true challenges of head and neck imaging. The organ is small and in almost constant motion. Breathing and swallowing create significant artifacts that can be controlled only briefly. The quality of laryngeal images has always been related to acquisition speed, and today, with multidetector spiral CT scanning and fast MRI techniques, excellent images can be achieved. Multidetector CT scanners can now cover the entire larynx in the time that, just a few years ago, could produce only a single axial image. The information obtained by modern imaging, when combined with the surface visualization of modern laryngoscopy, provides excellent understanding of pathology of the larynx.

This chapter first discusses the normal anatomy as seen using various imaging modalities. A discussion of the alterations of this anatomy, as a result of various types of pathology, follows. For completeness, some processes in which imaging is seldom helpful are also included. A discussion of the laryngopharynx (hypopharynx) is included because of its intimate relationship to posterior aspects of the larynx.

SECTION ONE

ANATOMY

There are three main functions of the larynx. The first, and most critical, is maintenance of the airway. The second is to help protect against aspiration, and the third is phonation. The anatomy[1] of the larynx is complex. It is a relatively tubular or cylindrical system of mucosal folds separated from an outer cartilaginous skeleton by intervening spaces filled with fat and muscle. Direct visualization of the endolarynx shows obvious landmarks including the epiglottis, aryepiglottic folds, false cords (folds), and true vocal cords (folds).

The region of the true cords, false cords, and intervening ventricle is particularly important in organizing the anatomy of the larynx. The true and false cords (vocal folds and vestibular folds) are axially oriented parallel structures situated at approximately the midlarynx along the craniocaudal axis. They extend from anterior to posterior, lying along the lateral aspect of the airway. The true cords converge anteriorly to attach to the midregion of the fused portion of thyroid cartilage. The vocal ligament is a thin fibrous band within the free margin of the true cord that extends the full length of the true cord from the vocal process of the arytenoid cartilage to the anterior commissure. The term *anterior commissure* refers to the region of the attachment of the vocal ligaments to the cartilage. This region includes the anterior cord, the thyroid cartilage, and Broyles' ligament, a fibrous structure connecting the vocal ligaments to the cartilage. Notably there is no perichondrium at that point, so the fibers extend directly from the vocal ligament into the structure of the cartilage.[2, 3]

The tubular airway extending from the cranial margin of the larynx to the level of the true vocal cords is referred to as the laryngeal vestibule. It has a circular or oval cross-sectional shape, and it is bounded by the epiglottis and the aryepiglottic (AE) folds. The AE folds sweep downward and posteriorly from the lateral margins of the midline anterior epiglottis to the arytenoid cartilages, just lateral to the midline in the posterior larynx. In the free posterior edge of the AE fold on either side, there are two small bumps or prominences. The more cranial one is the cuneiform cartilage, and the more caudal one is the corniculate cartilage. The corniculate cartilage is perched upon the superior aspect of the arytenoid cartilage. The interarytenoid area forms the posterior margin of the entrance to the larynx. Along the lateral surface of each AE fold is the pyriform sinus, which is actually an anterior recess of the hypopharynx (see also Chapter 28) (Figs. 30-1 and 30-2).

The skeleton of the larynx is made up of cartilage, fibrous sheets, and bands (Figs. 30-3 to 30-5). The cricoid cartilage is the only complete ring in the respiratory system and represents the foundation of the larynx. The shape of the cricoid cartilage resembles a signet ring with the quadrate lamina, or larger ''signet'' part, facing posteriorly. There is a vertically oriented midline ridge on the posterior surface of the quadrate lamina. The lateral aspect of the cricoid tapers gradually downward toward the much thinner anterior arch.

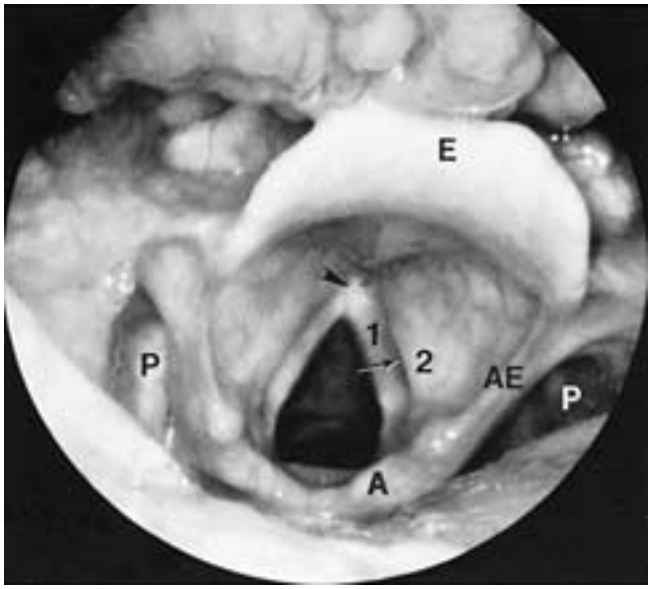

FIGURE 30-1 Endoscopic view of the larynx. *1*, True vocal cord; *2*, false vocal cord; *E*, epiglottis; *AE*, AE fold; *A*, arytenoid prominence; *P* pyriform; *arrowhead*, anterior commissure. Arrow points to the entrance of the ventricle. (From Hanafee W. Hypopharynx and larynx. In: Valvassori GE et al., eds. Head and Neck Imaging. New York: Thieme, 1988.)

VIEW IMAGE

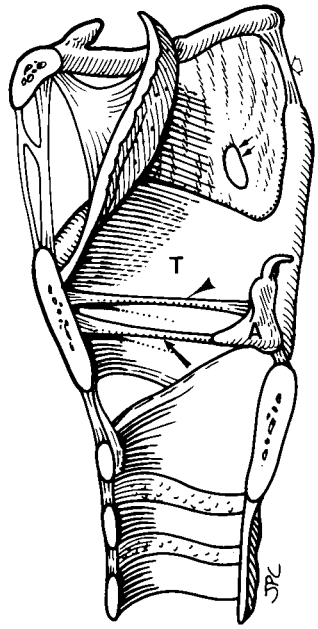
FIGURE 30-2 **A**, Lateral wall of the airway. The larynx has been sectioned sagittally in the midline. The true cord (*arrow*) and the false cord (*large arrowhead*) are separated by the slit-like ventricle. *Small arrowheads*, AE fold; *T*, thyroid cartilage; *C*, lamina of the cricoid cartilage (the projection of the arch of the cricoid is seen as a dashed line); *HE*, hyoepiglottic ligament; *E*, epiglottis. **B**, The mucosa of the true cord has been excised, showing the thyroarytenoid muscle (*arrows*) paralleling the margin of the true cord (*arrowhead*).

The lower edge of the entire cricoid is at the same horizontal level and defines the caudal aspect of the larynx. On either side, at the junction of the lateral arch and the quadrate lamina, there is a small facet for the articulation of the inferior horn of the thyroid cartilage. On the upper surface of the cricoid lamina are two paired articular facets, the cricoid portions of the cricoarytenoid joints (Figs. 30-4 and 30-6).



VIEW IMAGE

FIGURE 30-4 Lateral diagram of the larynx with the mucosa, laryngeal muscles, and paraglottic fat removed to show the skeleton of the larynx. The vocal ligament (*arrow*) stretches from the vocal process of the arytenoid (*A*) to the anterior thyroid cartilage. The ventricular ligament (*arrowhead*) stretches from the upper arytenoid to the thyroid cartilage. The small structure at the upper tip of the arytenoid is the corniculate cartilage. The lamina of the thyroid cartilage is represented by the letter T. The small hole (*double small arrows*) in the thyrohyoid membrane transmits the internal branch of the superior laryngeal nerve and the accompanying vessels. The posterior thyrohyoid ligament (*open arrow*) represents the posterior margin of the thyrohyoid membrane.

These facets are approximately 5 to 8 mm lateral to the midline.

The largest cartilage is the double-winged thyroid cartilage, with prominent superior and inferior cornua projecting from the posterior margin of either side of the

thyroid ala (wings). The lower cornu articulates with the lateral facets of the cricoid cartilage, forming the cricothyroid joint. The superior thyoid cornu is connected to the dorsal tip of the greater cornu of the hyoid bone by the thyrohyoid ligament. The remaining gap between the upper surface of the thyroid cartilage and the hyoid bone is filled by the tough thyrohyoid membrane. There is a deep thyroid notch in the midline of the superior margin of the thyroid cartilage. Where the thyroid alae join at the bottom of this notch, there is a prominence that forms the Adam's apple. Thus, the fused portion of the thyroid cartilage extends from the bottom of the superior thyroid notch to the caudal margin of the anterior thyroid cartilage and, as mentioned, the anterior commissure is situated on the inner surface of the cartilage near the midpoint of this fused region. The thyroid and cricoid cartilages act as the external protective shield for the inner larynx.

On the outer lateral surface of the thyroid cartilage is the oblique line extending downward and anteriorly from the root of the superior thyroid cornu toward the lower border of the thyroid ala. The sternothyroid muscle, thyrohyoid muscle, and inferior pharyngeal constrictor muscles attach to this line.

Perched on the superior edge of the cricoid cartilage are the paired arytenoid cartilages. Each arytenoid cartilage is roughly pyramid-shaped. At the level of the arytenoid cartilage base (inferior aspect) are two projections: the muscular process, situated on the posterolateral margin, and the vocal process located anteriorly. The vocal ligament attaches to the vocal process of the arytenoid cartilage (Figs. 30-4 and 30-6). The superior process represents the apex of the pyramid, and the corniculate cartilage rests on this margin. The vertical height of the arytenoid cartilage spans the laryngeal ventricle. The vocal and muscular processes are at the level of the true cord, while the superior process is above the level of the ventricle at the level of the false cord.

The cricothyroid, cricoarytenoid, and corniculate-arytenoid joints are all true synovial joints and subject to all of the diseases that may afflict such joints.

The cricoid, thyroid, and arytenoid cartilages are all hyaline cartilages and ossify to varying degrees. Ossification occurs via an endochondral process, as found in the long bones of the extremities. Normally, the perichondrium of these cartilages is quite resistant to penetration of blood vessels. However, along the lines of attachment of the muscular ligamentous attachments to these cartilages, fibers violate the perichondrium and allow blood vessels to enter the cartilage. It is from these points that enchondral ossification proceeds. Thus, the first regions of the laryngeal cartilages to ossifiy are along the lines of attachment of the muscles to these cartilages. Unfortunately, ossification proceeds in a quite variable manner, and asymmetry between the left and right sides is common. In the ossified portions of the laryngeal cartilages, fatty marrow develops. As will be discussed later, these areas of ossification, intermixed with regions of nonossified cartilage, may confuse the imaging evaluation of cartilage invasion. In addition, cartilage is normally quite resistant to tumor invasion, while bone is not. Thus, the areas of ossified cartilage are more prone to direct tumor invasion from carcinomas arising within or adjacent to the larynx.

By comparison, the epiglottis consists of yellow elastic fibrocartilage and, unlike the hyaline cartilages, seldom calcifies unless damaged, usually by a granulomatous process. The epiglottis is extremely flexible and has a ''memory'' allowing it to return to its normal shape after being bent nearly to a right angle. The epiglottis has a flattened teardrop shape that tapers to an inferior point called the petiole. Although the major portion of the epiglottis extends down behind the protective shield of the thyroid cartilage, a small portion, often referred to as the suprahyoid epiglottis, extends above the level of hyoid bone. Although the suprahyoid portion of the epiglottis is a continuous sheet of cartilage, the laryngeal portion of the epiglottis is perforated with numerous holes. As a result, whenever a process is on the laryngeal mucosal surface of this cartilage, it is pathologically considered to have extended through the cartilage. The epiglottic cartilage is stabilized by the hyoepiglottic and thyroepiglottic ligaments. The thryroepiglottic ligament attaches to the inner cortex of the thyroid cartilage just above the anterior commissure. The hyoepiglottic ligament extends from the hyoid bone to the anterior surface of the epiglottis, and the mobile or flexible portion of the epiglottis lies cranial to this attachment. The laryngeal portion of the epiglottis lies caudal to this level, between the hyoepiglottic and thyroepiglottic ligaments. Along with the free edge of the epiglottis and the AE folds, the hyoepiglottic ligament defines the cranial margin of the larynx.

As mentioned, there are three smaller paired cartilages in the upper larynx. They are usually not radiologically significant, but are occasionally visualized. The corniculate cartilages are small and sit immediately superior to the arytenoid cartilages (Fig. 30-4). They may not be distinguished from the larger arytenoid cartilages or they may be seen as a small bump in the lowermost AE fold. Slightly lateral and cranial to the corniculate cartilages, buried in the

free edge of the AE folds, are the thin cuneiform cartilages, which are almost never visualized on sectional imaging. The triticeal (tritiate or triticeous) cartilage (cartilago triticea) is located in the thyrohyoid ligament in the posterior edge of the thyrohyoid membrane. This cartilage frequently calcifies and on plain films may mimic a foreign body.

The hyoid bone is the ''rafter'' from which the larynx is suspended. Muscles acting on the hyoid bone elevate the larynx and move it ventrally, providing the primary protection from aspiration. The hyoid bone is U-shaped, having an anterior body and two large (greater) cornua that project posteriorly. Two small (lesser) cornua project superiorly from the hyoid body. The stylohyoid ligaments attach to these lesser cornua. A sagittal section through the hyoid body has the shape of an inverted L open posteriorly and inferiorly.

Two parallel ligaments extend anteriorly from each arytenoid cartilage to attach to the inner lamina of the thyroid cartilage (Fig. 30-4). The more inferior vocal ligaments stretch from the vocal process of each arytenoid cartilage anteriorly to reach the anterior commissure, which, as mentioned, is in the middle third of the posterior surface of the midline thyroid cartilage. This vocal ligament forms the medial support of the true vocal cord.

The more superior ventricular ligament attaches to the anterior superior surface of the arytenoid cartilage and stretches across the larynx (parallel to the vocal ligament) to attach to the inner lamina of the thyroid cartilage just above the anterior commissure. This ligament is actually the lower free margin of the quadrangular membrane and supports the free edge of the false cord.

On either side, the quadrangular membrane is a fibrous sheet-like structure that extends from posteriorly, where it attaches to the upper arytenoid and corniculate cartilages, to anteriorly, where it attaches to the lateral margin of the epiglottis (Fig. 30-7). The anterior border of the quadrangular membrane is broader than the posterior edge. The lower margin is free, representing the ventricular ligament. The upper margin forms the support of the aryepiglottic fold. This membrane is just beneath the mucosa of the upper larynx and forms the medial boundary of the paraglottic space (see below).

A second membrane or fibrous layer, the conus elasticus, stretches downward from the vocal ligament of the true cord to attach to the upper inner margin of the cricoid cartilage (Fig. 30-7). Although some fibers of the conus may reflect along the inner margin of the cricoid to its lower inner surface, for purposes of this discussion it will be considered that the conus attaches primarily to the superior cricoid margin. The conus elasticus is a thicker, more clearly defined membrane than the quadrangular membrane. The conus spans part of the gap between the thyroid and cricoid cartilages and can be considered to consist of two parts. The lateral part extending from the vocal ligament to the cricoid cartilage is called the lateral cricothyroid ligament (cricovocal membrane). The anterior part of the conus is the anterior (or median) cricothyroid ligament, which extends in the midline from the lower margin of the thyroid cartilage to the upper margin of the arch of the cricoid. Fibers from these two parts merge together, and the entire complex taken together is called the conus elasticus. There are small gaps just lateral to the median cricothyroid ligament where the

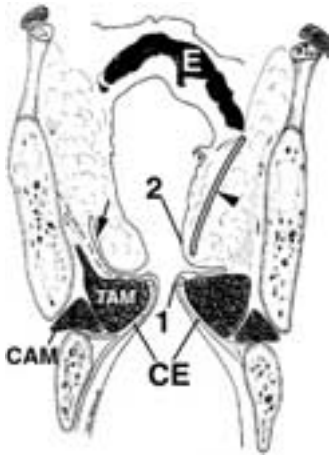

FIGURE 30-7 Diagram of a coronal section through the larynx. The thyroarytenoid muscle (*TAM*) forms the mass of the true cord. The lateral cricoarytenoid muscle (*CAM*) is seen slightly laterally and inferiorly. The conus elasticus (*CE*) extends from the vocal ligament at the cord level to the upper margin of the cricoid. On the left side of the diagram, the conus terminates at the upper margin of the cricoid cartilage. On the right side of the diagram, some fibers of the conus continue along the medial surface of the cricoid, as described by some authors. The paraglottic space is the soft tissue separating the quadrangular membrane and conus elasticus from the cartilage framework. *E*, Epiglottis; *1*, true cord; *2*, false cord; *arrowhead*, quadrangular membrane; *arrow*, ventricular appendix extending superiorly into the paraglottic space. VIEW IMAGE

lowermost portion of the paraglottic space of the inner larynx is continuous with the extralaryngeal tissues.

As was previously mentioned, the primary supports of the epiglottis are the hyoepiglottic and thyroepiglottic ligaments. The hyoepiglottic ligament is a tough fibrous structure that extends from the ventral midline of the epiglottis to the dorsal margin of the body of the hyoid bone (Fig. 30-2). This fan-like ligament not only marks the line of separation between the suprahyoid and infrahyoid (laryngeal) portions of the larynx but is also considered the anterior upper margin of the larynx.[4] Immediately cranial to this ligament is the mucosa of the pharyngeal recesses referred to as the valleculae. They are formed by the three mucosal folds, the midline (median) glossoepiglottic fold and two more lateral pharyngoepiglottic folds. The valleculae are situated just caudal to the base of the tongue. Lingual tonsillar tissue may extend down along the anterior surface of the valleculae, but will not normally extend either into the floor or along the posterior mucosal surface of the valleculae.

Inferiorly the thyroepiglottic ligament extends from the petiole of the epiglottis to the midline inner surface of the thyroid cartilage just above the attachment of the anterior commissure. The epiglottis is also partially supported on either side by the quadrangular membranes.

One final membrane or fascial sheet should be mentioned. The thyroglottic ligament is described by Sato et al. as passing through the supraglottic fat (see Fig. 30-7).[5] This fascia is reported to sweep downward from its attachment to the inner lamina of the thyroid cartilage and is considered in descriptions of the paraglottic space. The layer passes around the lateral aspect of the ventricle to merge

Copyright © 2003, Mosby, Inc. All rights reserved.

with the vocal ligament and thyroarytenoid muscle. This ligament or fascial layer may be variable, but it is distinct from the quadrangular membrane.

The laryngeal muscles are described in terms of their origins and insertions. To the radiologist, the most important muscle is the thyroarytenoid muscle (TAM) because of its role as a landmark defining the level of the true vocal cord (Figs. 30-2, 30-6, 30-7 and 30-8).

Each TAM stretches from the anterior lower surface of the arytenoid cartilage to the inner aspect of the thyroid cartilage, paralleling the vocal ligament. Some fibers attach to the conus elasticus. The TAM is responsible for most of the bulk of the true cord, and has a medial belly and a lateral belly that run roughly parallel to each other. The medial portion, also called the vocalis muscle, consists of more parallel muscle fibers that form the medial part of the cord. The lateral belly forms the main bulk of the TAM and thus the true cord. Although most muscle fibers remain at the level of the true cord, a few fibers can extend superiorly to insert high on the thyroid cartilage above the level of the ventricle. The posterior space between the vocal cords at the level of the vocal processes of the arytenoid cartilages is referred to as the posterior commissure.

FIGURE 30-8 Coronal section of the larynx. The bulk of the true cord consists of the thyroarytenoid muscle (*TA*). The ventricle (*v*) is seen between the true and false cords. The paraglottic space (*arrowhead*) at the level of the false cord contains small slips of muscle but is filled predominantly with fat. *T*, Thyroid cartilage; *C*, cricoid cartilage; *E*, epiglottic cartilage.

The posterior cricoarytenoid muscle is totally responsible for abduction of the true cord as the muscle pulls posteriorly on the lateral muscular process of the arytenoid. *C*, Conus elasticus; *L*, vocal ligaments.

VIEW IMAGE

Of equal importance to the function of the larynx, but not as crucial to the radiologist, are the cricoarytenoid muscles (Fig. 30-9). The lateral cricoarytenoid muscle stretches from the muscular process of the arytenoid to the upper lateral surface of the cricoid cartilage. The posterior cricoarytenoid muscle stretches from the posterior surface of the cricoid to the muscular process of the arytenoid. These small antagonistic muscles frequently can be identified on CT and MR imaging. The posterior cricoarytenoid muscle is the only muscle that directly swings the vocal cord laterally (abduction). The interarytenoid (transverse and oblique arytenoid) muscles stretch from one arytenoid to the other, completing the midline posterior wall of the larynx above the cricoid. The lateral cricoarytenoid and the interarytenoid muscle both adduct the true cords. The interarytenoid muscles are the only laryngeal muscles to have bilateral innervation from the recurrent laryngeal nerves; all of the other intrinsic muscles are innervated either by the left or the right recurrent laryngeal nerves (X). The cricothyroid muscle extends from the lower thyroid cartilage to the upper cricoid cartilage and is the only extrinsic laryngeal muscle. It is also the only laryngeal muscle supplied by the external branch of the superior laryngeal nerve (X). Small muscular slips are also present in the upper larynx. These include the thyroepiglotticus and the aryepiglotticus.

Copyright © 2003, Mosby, Inc. All rights reserved.

The pharyngeal constrictors attach posteriorly to a midline raphe and then sweep obliquely around the lumen of the pharynx to attach to the hyoid bone above and to the sides of the cricoid and thyroid cartilages more inferiorly. Notably the fibers attach to the lateral ala of the thyroid cartilage, not along the posterior margin of the cartilage, but along the oblique line on the lateral surface of this cartilage. This becomes important when evaluating pharyngeal tumors, as described in a later section. The pharyngeal constrictors are innervated by the pharyngeal plexus, with a major contribution from the vagus nerve (X) and a lesser contribution from the glossopharyngeal nerve (IX).

The muscle fibers of the three pharyngeal constrictors are attached in the posterior midline to a raphe. The fibers then extend obliquely downward to their attachment on the laryngeal cartilages. However, the lowermost fibers of the inferior pharyngeal constrictor are not attached to the midline raphe. These parallel fibers are continuous around the pharynx and are referred to as the cricopharyngeus. Between the lower edge of the oblique fibers of the inferior pharyngeal constrictor and the upper surface of the cricopharyngeus is a triangular space not supported by muscle, referred to as Killian's dehiscence. It is through this area that a Zenker's diverticulum extends. The cricopharyngeus is a sphincter between the pharynx and the esophagus that prevents esophagopharyngeal reflux. It also must open the gullet during swallowing (see Chapter 32). Anterior midline longitudinal fibers of the esophagus extend above the level of the cricopharyngeus to attach to the midline vertical crest on the posterior cricoid cartilage.

Spaces

The outer boundary of the larynx is formed by the lower hyoid bone, the thyrohyoid membrane and ligaments, the thyroid cartilage, the cricothyroid membrane, and the cricoid cartilage. Between this outer boundary and the mucosal surfaces of the larynx are spaces.

The preepiglottic space is an anterior space between the ventral surface of the epiglottis (posterior margin) and the anterior boundary of the larynx extending from the lowermost hyoid bone to the midthyroid cartilage (anterior margin). The cranial limit of this space is the thyrohyoid ligament, and the caudal limit is the thyroepiglottic ligament. The preepiglottic space is filled with fat and has a rich lymphatic and microvascular network.

The paraglottic space represents the deeper soft tissue of the lateral wall of the larynx. As described by Tucker and Smith, this area is bounded medially by the quadrangular membrane in the upper larynx and the conus elasticus in the lower larynx.[6, 7] The lateral boundary is the cartilaginous skeleton of the larynx represented predominantly by the thyroid cartilage (Figs. 30-7 and 30-8). The paraglottic space is the region deep to the mucosal surfaces of the true and false cords. At the false cord level, the paraglottic space is almost entirely composed of the fat lying between the quadrangular membrane and the thyroid cartilage. Although small slips of TAM may cross the space, no bulky muscle is present.

The laryngeal ventricle extends laterally into each space; however, the ventricle does not reach the inner surface of the thyroid cartilage. A narrow band of paraglottic fat is present lateral to each ventricle, and the paraglottic space is continuous from the level of the false cord to the level of the true cord, passing along the lateral aspect of the ventricle. At the level of the true cord, the TAM fills almost all of the paraglottic space (Fig. 30-8). The conus elasticus forms the lower boundary of the paraglottic space. However, the paraglottic space is not completely closed because, laterally and anteriorly, there is no major fascial barrier closing the space between the cricoid and thyroid cartilages. Thus, through this region the paraglottic space is continuous with the extralaryngeal soft tissues.

The terminology referring to this space is not universally accepted, and some authors describe the paraglottic space as being lateral to a thin membrane referred to as the thyroglottic ligament.[5, 8, 9] This ligament is described as arising from the inner surface of the thyroid cartilage above the ventricle and then sweeping downward and medially to reach the vocal ligament. Using this definition, there would be fat between the quadrangular membrane and the paraglottic space. This fat is considered a posterior extension of the preepiglottic fat. Tucker and Smith also described this thyroglottic ligament, but showed it to partially segment the paraglottic space rather than forming a complete boundary.[6] This chapter will use the terminology as originally presented by Tucker and Smith, and the paraglottic space will refer to all tissue between the quadrangular membrane and the outer cartilaginous laryngeal skeleton. The thyroglottic ligament lies within this space rather than forming a boundary of the space.

At the level of the false cord, a small recess projects superiorly from the anterior laryngeal ventricle into the paraglottic fat. This recess, called the laryngeal saccule or appendix, lies between the quadrangular membrane and the thyroid cartilage. Dilatation of the saccule causes a supraglottic cyst called a laryngocele.

The pyriform sinus is an anterior mucosa-lined recess of the hypopharynx situated between the medial aspect of the posterior one third of the thyroid cartilage and the lateral surface of the AE fold (Fig. 30-10). The anterior wall of much of the pyriform sinus is the posterior wall of the paraglottic space. The lowest aspect of the pyriform sinus, the apex, reaches the level of the true vocal cord, between the arytenoid cartilage and the thyroid cartilage. At imaging, this area, with a small amount of fat just deep to the mucosa, has been referred to as the thyroarytenoid gap.

Innervation and Blood Supply

The larynx is innervated by branches of the vagus nerve. The recurrent laryngeal nerve loops around the aortic arch on the left side and the subclavian artery on the right. Each nerve then travels in the tracheoesophageal groove at the anterolateral margin of the esophagus. Each nerve passes medial to the lower margin of the cricopharyngeus muscle and enters the larynx in the sulcus between the thyroid cartilage and the cricoid cartilage just above the cricothyroid joint. The recurrent laryngeal nerve innervates all of the intrinsic muscles of the larynx.

As mentioned, the only extrinsic laryngeal muscle, the cricothyroid muscle, is innervated by the external branch of the superior laryngeal nerve. This external branch never

FIGURE 30-10 A view from posterior and to the left with the pharynx open. (Modified from Berman JM. Surgical anatomy of the larynx. In: Bailey BJ, Biller HF. Surgery of the Larynx. Philadelphia: WB Saunders, 1985; 20.)

enters the larynx. The internal branch of the superior laryngeal nerve does perforate the posterior lateral portion of the thyrohyoid membrane, providing sensation to the laryngeal mucosa.

The blood supply to the larynx accompanies the nerves. The superior laryngeal artery is a branch of the superior thyroid artery and follows the internal branch of the superior laryngeal nerve. The inferior laryngeal artery is a branch of the inferior thyroid artery, which in turn is a branch of the thyrocervical trunk. The inferior laryngeal artery accompanies the recurrent laryngeal nerve into the larynx.

Lymphatic Drainage

The lymphatic drainage of the deep larynx passes almost completely cephalad, as the supraglottic larynx is considered a derivative of the pharynx. The thyroid cartilages form from two centers, one on either side of the midline, and injection studies have shown that the submucosal lymphatics follow this bilateral developmental scheme and do not cross the midline.[10–12] However, the mucosa of the supraglottic larynx forms as a single structure, after development of the cartilage, and the mucosal lymphatics do cross the midline. The lymphatics of the supraglottic larynx drain superiorly through the thyrohyoid membrane to the upper jugular nodes (levels II and III).

The lymphatics of the subglottic larynx also drain in a cephalad direction. The low subglottic lymphatics drain slightly upward to and then through the cricothyroid membrane to the paratracheal and pretracheal nodes (level VI). The studies of Pressman et al. showed again that dye injections deep to the mucosa did not cross the midline, but that once the dye passed through the cricothyroid membrane, the subsequent drainage was bilateral. Mucosal dye injections ended abruptly at the lower margin of the cricoid cartilage and did not extend to the trachea. The lymphatic flow of the upper part of the subglottic larynx is also primarily cephalad, extending beyond the ventricle to the paraglottic network of the supraglottic larynx. The submucosa of the true cord has almost no lymphatic drainage.

The preepiglottic and paraglottic spaces are particularly rich in lymphatics, and the greater the tumor infiltration into these areas, the more likely it is that there will be cervical metastatic nodal disease. The Delphian node is anterior to the cricothyroid membrane. Tumor can reach this region either by direct extension or by lymphatic drainage from a tumor in the region of the anterior commissure and the subglottic larynx. Enlargement of this node has been suggested as an early clinical manifestation of the presence of subglottic tumor. Most commonly, the region in which this node is located is affected secondary to direct tumor extension, without involvement of a separate definable node.

The concept that the lymphatics of the deep portion of the larynx flow almost exclusively in the cephalad direction is important when planning a partial laryngectomy.

Regions

Certain anatomic terms are important when describing the larynx, particularly when discussing tumors. The larynx is subdivided by two theoretical horizontal (axial) planes; one extends through the apex of the two laryngeal ventricles, and the other parallel plane is 1 cm caudal to the first. The supraglottic larynx is that portion of the larynx cranial to the first plane or superior to the plane of the ventricle. This includes the epiglottis, AE folds, false cords, and so on. The upper margin of the supraglottic larynx, as described previously, is the free edge of the epiglottis and the AE folds and, more anteriorly, the hyoepiglottic ligament. The upper arytenoid cartilages are included in the supraglottic larynx. The glottis is the region between the two planes and includes the anterior and posterior commissures. The subglottis is the region between the lower plane and the inferior (caudal) margin of the cricoid cartilage.

The supraglottic larynx can be subdivided into infra- and suprahyoid regions separated by the hyoepiglottic ligament. The suprahyoid portion of the epiglottis is often called the free segment. The anterior surface of the free segment of the epiglottis, as well as the valleculae, are often included in discussions of the base of the tongue and the pharynx.

The postcricoid region is the mucosal covering of the posterior surface of the cricoid cartilage, representing the anterior wall of the hypopharynx at this level. Because of its relationship to both the pharynx and the larynx, the free edge of the AE fold is at times referred to as the junctional or marginal zone.

SECTION TWO

IMAGING

In this section, the various imaging modalities are discussed and the normal laryngeal anatomy visible on each examination is shown.[13–18] Several radiographic procedures are included for historical perspective, but are currently seldom if ever performed. A review of certain respiratory maneuvers is included because they can be used to accentuate different areas in the larynx during imaging. Although these respiratory maneuvers were used extensively with laryngography and multidirectional tomography, they were not as useful with earlier CT and MR imaging due to the longer imaging times they required. However, with today's faster imaging, examinations in different respiratory phases are again possible. The coronal plane is ideal for appreciating these movements, so some tomographic images are used for illustration.

Respiratory Maneuvers

In quiet respiration, the vocal cords are slightly separated from the midline but are not completely effaced against the lateral laryngeal wall. In the coronal plane, the cord is seen to have a flat upper surface and a lower downward-sloping surface that extends to the lateral wall of the subglottic laryngeal airway. This slope has been referred to as the subglottic arch. Although this slope is seen in quiet respiration, it is more pronounced in phonation. With slow inspiration the true cords and false cords further abduct, disappearing on imaging as they flatten against the now smooth lateral wall of the larynx. When the patient holds his or her breath and bears down (Valsalva maneuver), the cords go to the midline (adduct), squaring off the subglottic arch and forming the subglottic angle (between the inferior surface of the cord and the lateral wall of the airway). No airway is seen at the true cord level, and the false cords also approximate in the midline. The modified Valsalva maneuver is performed with the cheeks puffed and the patient allowing air to escape slowly from the mouth. This maneuver not only puffs the cheeks, but also dilates the pyriform sinuses and all the airway structures above the true cords. With phonation (the patient makes a high-pitched ''eeee'' sound), the cords tense and approach the midline, leaving a narrow airway. The ventricle may be expanded or collapsed in any maneuver. The reverse, or inspiratory ''e'' maneuver, usually dilates the ventricle. Although this maneuver may be difficult for many patients, usually any noise made while breathing in will suffice.

Although these maneuvers are expected to produce the described effects, many times the particular structure the radiologist is trying to visualize shows up on the ''wrong'' maneuver. A tomographic examination typically includes all of these maneuvers (Figs. 30-11 and 30-12).

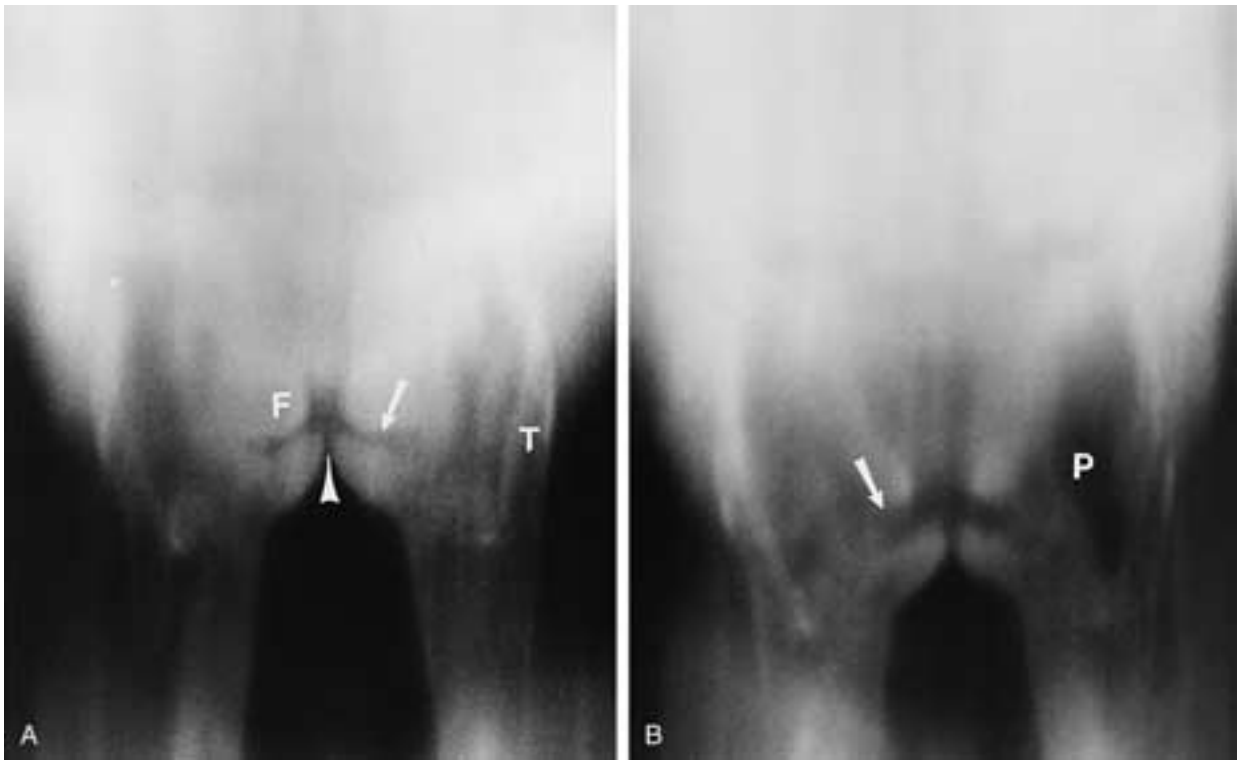

FIGURE 30-11 **A**, Coronal tomograms during phonation. The true cords approximate with only a small residual airway (*arrowhead*). The ventricle (*arrow*) is partially filled with air. *T*, Thyroid cartilage; *F*, false cord. **B**, Reverse phonation shows more dilatation of the ventricles (*arrow*). *P*, Pyriform sinus.

The AE fold (*small arrowheads*) and the inner wall of the larynx (*large arrowhead*) are well demonstrated. *V*, Valleculae.

Plain Film Radiography

The plain film soft-tissue technique uses less kilovoltage than that used for cervical spine films. These soft-tissue films of the neck use the normal air present in the upper airway to contrast the adjacent soft tissues of both the larynx and trachea (Fig. 30-13). The retropharyngeal soft-tissue thickness also can be appreciated on lateral films. The epiglottis and the AE folds usually are well visualized, and air in the ventricle often marks the position of the upper margin of the true cord. Portions of the cartilages can be visualized, depending on the degree of ossification.

The variability of ossification of the laryngeal cartilage makes any prediction of pathology affecting these cartilages hazardous on the plain films. Frequently the partly calcified cartilages create a diagnostic problem for the radiologist examining for foreign bodies. Because of this, the radiologist should be familiar with the most common pitfalls or false foreign bodies.

The superior margin of the cricoid lamina often calcifies early, before the remainder of the signet portion of the cricoid (Figs. 30-13 and 30-14). This linear calcification is easily mistaken for a foreign body. The triticeal cartilage in the posterior thyrohyoid ligament is another foreign body mimic (Fig. 30-14). Less commonly a calcified arytenoid or the cornua of the thyroid cartilage may be mistaken for a foreign body.

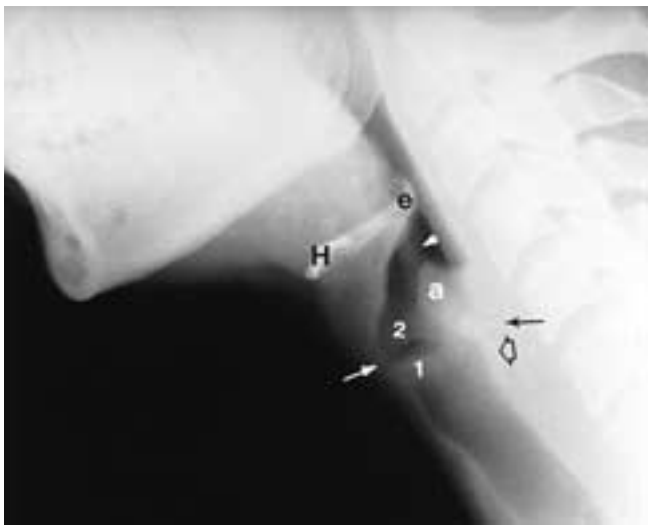

FIGURE 30-13 Lateral plain film of the neck shows the true cord (*1*) and the false cord (*2*) separated by the black air-filled linear ventricle. The white arrow points to the anterior ventricle. The anterior commissure (junction of the true cords) is just inferior to this point. The black arrow shows the calcified superior margin of the cricoid lamina, which is often mistaken for a foreign body. The open black arrow shows the calcified lower horn of the thyroid cartilage. *H*, Hyoid; *a*, arytenoid prominence; *e*, epiglottis; *arrowhead*, AE fold.

This cartilage is located in the posterior thyrohyoid membrane. The upper edge of the cricoid (*lower black arrow*) is mineralized. Ventricle (*white arrow*).

VIEW IMAGE

High-kilovolt (140 kV) films are used to ''soften'' the spine, allowing visualization of the airway in the frontal projection. A 1 mm copper filter can be placed between the tube and the patient to give a lowered film contrast.[19, 20]

Xeroradiography used edge enhancement technology to clearly show the anatomy of the airway, cartilages, and even muscle and fat planes (Fig. 30-15).[21] This technique was considered ideal for visualizing foreign bodies and for evaluating the trachea (e.g., for subglottic stenosis, granuloma). However, xeroradiography has an exposure three to five times that of the standard soft-tissue film. Its use in imaging soft tissues and cartilage has been superseded by CT and MR imaging.

Tomography

Today, conventional linear or multidirectional tomography seldom is used for the evaluation of the larynx, though occasionally it is utilized to assess the trachea. Tomography allows visualization of the airway anatomy in the frontal view without the problems of superimposition of the density of the spine (Fig. 30-11). The exposure can be made in several seconds, rapidly enough that the various maneuvers (e.g., phonation, Valsalva) can be used to show specific anatomic landmarks in the coronal plane. Only the surface deformity is visualized by this technique, and the deep extent of a tumor is estimated by the degree of distortion of the false and true cords. As the pyriform sinus protrudes between the thyroid cartilage and the inner wall of the larynx, the width of the wall can be estimated in an attempt to show tumor extending through the paraglottic space toward the true cord. Subglottic extension is well seen by the flattening of the subglottic arch.

Because tomography requires multiple slices and multiple maneuvers, the examination has a fairly high radiation exposure. Every attempt is made to place the airway in the plane of section parallel to the tabletop. Placing a bolster under the buttocks, with additional support of the knees, allows positioning without forcing the patient to straighten the natural angle between the thoracic and cervical spines.

Fluoroscopy

Because some patients will not tolerate direct clinical visualization of the larynx without anesthesia and because some patients may have a tumor blocking the clinician's view, fluoroscopy can be helpful in assessing vocal cord mobility. This procedure requires that the patient be awake and able to follow verbal commands. The examination is recorded on videotape to allow review without additional patient exposure.

Contrast Examinations

Contrast laryngography was developed to better define mucosal irregularities.[22–24] The information derived from the laryngogram is now routinely obtainable by endoscopy, and the submucosal regions can be better visualized with CT and MR imaging. Contrast laryngography was difficult for many patients to tolerate, and this procedure was contraindicated in those patients who had partial airway obstruction secondary to tumor, thus limiting direct clinical examina-

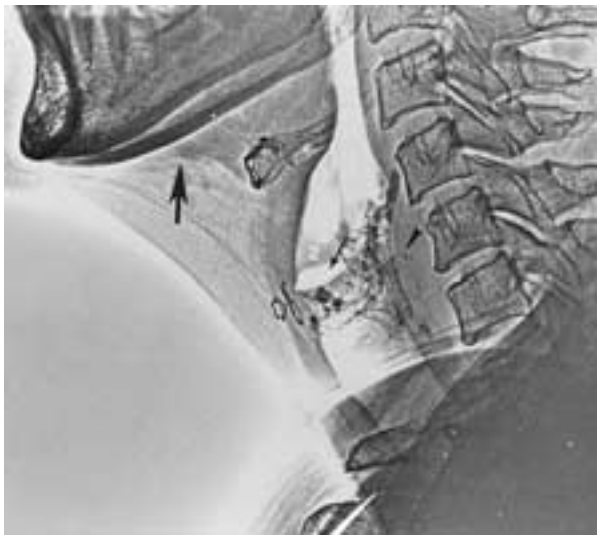

FIGURE 30-15 Xeroradiogram (lateral view) shows the true cord, false cord, and ventricle, with better definition of the fat planes. Note that the calcified upper margin of the cricoid lamina (*arrowhead*) is seen more obviously here than in Figure 30-13. tion. Unfortunately, these were the very patients who most needed such an examination. The examination is contraindicated in these patients because there is always some element of mucosal edema in response to the topical anesthetic and the contrast material, further narrowing an already compromised airway.

If there was no contraindication, the patient was given atropine (0.4 mg) and codeine (60 mg). The atropine decreased secretions, drying the mucosa, enabling better contrast coating, while the codeine limited coughing.

The anesthesia of the larynx was the most important part of the contrast laryngogram. After initial anesthesia with topical agents, a curved cannula was placed over the back of the tongue, and 2% xylocaine was dripped into the pyriform sinus and larynx as the patient breathed slowly in and out. Alternatively, a soft rubber tube was passed through the nose and directed over the larynx.

Some radiologists used 4% xylocaine, but with extreme caution. Xylocaine is rapidly absorbed through the mucosa and can precipitate cardiac arrhythmias, hypotension, or central nervous system aberrations.

Initially, the patient coughed as the xylocaine dripped into the laryngeal lumen, but as anesthesia occurred, the coughing stopped. The procedure continued with administration of the contrast medium. In the United States, oily propyliodone (Dionosil) was the most common contrast agent used. The contrast was warmed and mixed well, then dripped into the larynx using a syringe and a laryngeal cannula or nasal tube. The patient breathed in slowly as the contrast was administered, and the patient was asked to cough lightly to help distribute the contrast. Administration could be monitored in the lateral projection with intermittent fluoroscopy. The patient was placed in the frontal, lateral, and oblique positions and asked to perform the various previously described maneuvers (Fig. 30-12).

Historically, the laryngogram was considered especially helpful in imaging certain important areas of the larynx. The clinician's view of the ventricle and anterior commissure can be blocked by overhanging tumor. Phonation or inspiratory ''e'' may distend the ventricle. Because the two ventricles are superimposed on the lateral projection, frontal films were obtained to determine whether the ventricle filled on both sides. With modern endoscopy, these areas usually can be routinely visualized. The subglottic angle can be clearly defined with laryngography, but it is more easily assessed by CT or MR imaging.

Barium Swallow

The barium swallow is used to evaluate the pharyngeal wall. The barium column is followed through the pharynx into the esophagus. The motility and pliability of the pharyngeal wall and the mucosal surfaces are assessed. Demonstration of normal pliability of the pharyngeal wall suggests normal tissue. Tumor infiltration causes lack of pliability or distensibility, as well as mucosal irregularity (Fig. 30-16).

In the frontal view, the pyriform sinuses fill as the epiglottis deflects the barium column to either side, around rather than over the vestibule of the larynx (Fig. 30-17). As the larynx elevates, the pyriform sinuses lose their sharply curved lower borders, becoming continuous with the remaining hypopharynx. The barium is propelled through the cricopharyngeus into the esophagus. As the barium column splits to pass through the pyriform sinuses, the larynx becomes a ''filling defect'' in the barium column and should not be mistaken for a mass.

On the lateral view, the cricopharyngeus opens as the pharynx propels the bolus toward the pharyngoesophageal junction. The cricopharyngeus is inspected for late or incomplete relaxation and for the formation of an outpouching such as a Zenker's diverticulum. On the lateral film, irregularity is often seen on the anterior wall of the lower pharynx in the postcricoid area. This has been described as being due to a venous plexus or to normal mucosal redundancy, and at times differentiation from a tumor may be impossible. The relationship of the posterior pharyngeal wall to the cervical spine and possible anterior vertebral osteophytes is well seen in the lateral view.

Computed Tomography Scanning

CT scanning allows evaluation of the laryngeal structures deep to the mucosa.[24–26] A lateral scout view is obtained and the slice orientation is selected parallel to the laryngeal ventricle, seen as a dark air line in the laryngeal airway. If the ventricle is not seen well or if the airway is obscured by the shoulders in a patient with a short or thick neck, the slice orientation is estimated to be perpendicular to the axis of the spine at the level of the larynx. The axial images are made with a field of view corresponding to the size of the neck. The patient can pull on a strap passed around the feet to lower the position of the shoulders and diminish artifacts.

The use of sequential rapid (1 to 2 seconds) scanning can decrease respiratory and swallowing artifacts. The choice of slice thickness is arbitrary; however, most radiologists use either a 2 or 3 mm slice thickness. If the relationship of the lesion to the ventricle is still in question, once the area of the ventricle is identified, 1mm slices can be taken through the true cord–ventricle–false cord complex.

Spiral scanning rapidly acquires a complete data set through the larynx. The images then can be reconstructed to give overlapping slices at any level, and this is particularly helpful at the level of the ventricle. Coronal, sagittal, and even three-dimensional (3D) images can be generated from the same data set. The real advantage of spiral scanning is that the entire larynx can be examined in 10 to 20 seconds, and this minimizes motion artifact. In addition, with spiral CT scanning, examination of the larynx during respiratory maneuvers may be possible. This may be done to optimize visualization of a particular region of the larynx or the margin of a tumor. More clinical experience is necessary before the usefulness of these techniques is accepted. With new multidetector CT scanners, the collimation can be 1 mm and the larynx can be covered in a few seconds by varying the pitch of the scan.[27] Overlapping reconstructions can be made, giving excellent coronal reformatted images (Fig. 30-18). This technique makes correct patient positioning less important, as the recon-

FIGURE 30-16 Polypoid mass arising from the lateral wall of the pharynx. Pharyngogram using thicker barium. **A**, Anterior posterior view. The polypoid mass (*small arrow*) protrudes from the lateral wall of the pyriform sinus. Note the distention of the pyriform sinus (*small arrowheads*) as the patient puffs the cheek. There is distention of the pyriform apex (*large arrowhead*) on the opposite side. A small amount of contrast extends into the airway, coating the true cord (*large arrow*). *V*, Valleculae. **B**, Lateral view. The tumor (*T*) is seen contrasted against the distended pharynx. Note the coating of the laryngeal surface of the epiglottis (*arrowheads*) and the barium seen in the ventricle (*arrow*) along the upper margin of the true cord.

structed images can be adjusted to give images directly in the plane of the ventricle.

The region covered should extend below the level of the cricoid cartilage. The starting point can be the tip of the epiglottis or the hyoid bone, depending on the origin of the lesion (see the following discussions on squamous cell carcinoma, other malignancies, and benign tumors). If nodal regions are to be studied, the scan should start at the external auditory meatus. The examination can be done with the patient breathing quietly or breath-holding now that imaging speed is acceptable. Before the actual scan is started, the patient should practice any breathing maneuver, and the technologist should be confident that motion can be minimized during the scan. If the scan is done during quiet breathing, the patient should attempt as much as possible to breathe with the abdominal muscles, keeping the chest wall still. Intravenous contrast helps distinguish lymph nodes from blood vessels and thus is used in tumor cases, but it is not necessary in laryngeal trauma evaluation.

In the upper (cranial) axial slices, the epiglottis and connecting ligaments and folds (median glossoepiglottic and pharyngoepiglottic folds and the hyoepiglottic ligament) are seen (Fig. 30-19). More inferiorly, the lateral edges of the epiglottis merge with the AE folds, which in turn converge toward the midline and unite posteriorly at a more caudal level.

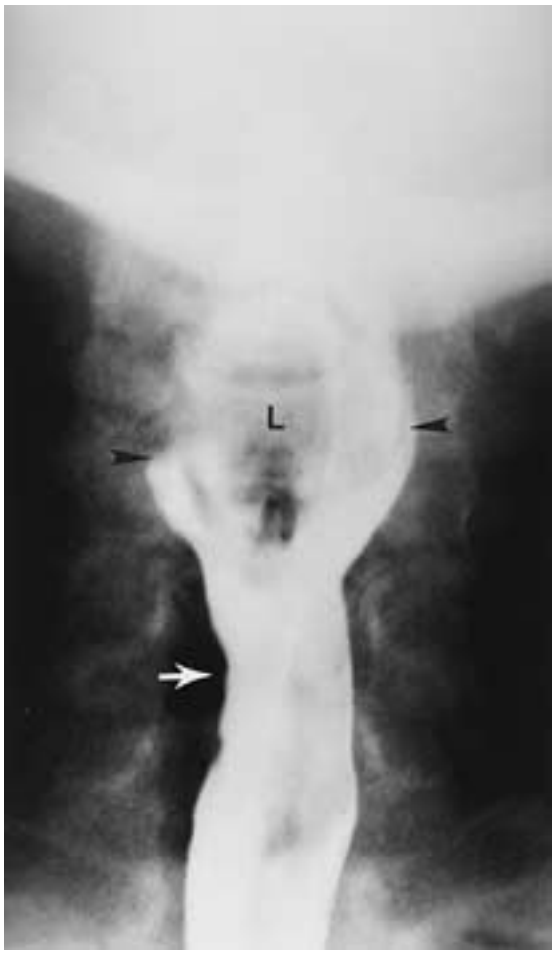
In the supraglottic larynx, the preepiglottic space is filled with fat, and portions of the hyoepiglottic ligament can be seen in the midline crossing the upper portion of this fat. The laryngeal vestibule has an ovoid shape, and the epiglottis may at times be partially folded upon itself. At the level of the false cords, the paraglottic region lateral to the airway is also predominantly fat density. As the axial slices pass the ventricle, the paraglottic space changes from predominantly fat density to muscle density (the thyroarytenoid muscle). The shape of the airway narrows at the cord level, becoming more slit-like, but then widening to a more oval or rounder appearance at the level of the subglottis. The paraglottic space, limited by the conus elasticus, stops at the upper margin of the cricoid. Thus there should be no soft tissue within the ring of the cricoid cartilage.

The appearance of the cartilage can vary considerably, depending on the degree of ossification and the amount of fatty marrow in the ossified medullary region. Both thyroid and cricoid cartilages are easily identified. The thyroid cartilage spans the level of the true and false cords. The axial slices are ideal for evaluating these cartilages, displaying them in perfect cross section. In general, the angle made by

Copyright © 2003, Mosby, Inc. All rights reserved.

the two thyroid alae is wider in women than in men. The arytenoid cartilages are important landmarks that can help identify the true cord, ventricle, and false cord relationships. Approached from cranially, the upper arytenoid is seen first at the level of the false cord as a square or triangular density. At more caudal levels, the anteriorly pointed vocal process can be identified projecting from the arytenoid base. The vocal process identifies the level of the true cord. Because the level of the vocal process is also at the level of the cricoarytenoid joint, the true cord level and the posterior commissure can be identified when the arytenoid cartilages are seen on the same axial scan as the top of the cricoid lamina. Unfortunately, there is no definite landmark on any of the cartilages that defines the exact level of the laryngeal ventricle.

The appearance of the vocal cords varies with the phase of respiration. In quiet breathing, the airway is open and the cords are slightly abducted. If the patient is breath-holding for each scan, the cords usually are adducted (Fig. 30-20). This maneuver may actually give a slightly clearer visualization of paraglottic fat along the outer lateral margin of the cords.



VIEW IMAGE

FIGURE 30-17 Frontal view of a barium swallow, normal. The barium (*arrowheads*) is deflected around the larynx, with an apparent filling defect caused by the larynx (*L*). The impression on the upper esophagus (*white arrow*) is caused by osteophytes.

The anterior commissure should have air closely approximating the cartilage. If this appearance is seen, the radiologist can be relatively confident that no disease is present at this site. On CT, obliteration of the anterior commissure can be seen secondary to tumor, but it may also be an artifact resulting from minor cord position changes or cord edema.

At the caudal margin of the cricoid cartilage, the appearance of the hypopharyngeal musculature changes from a flat, elongated semilunar appearance to a rounder ovoid configuration (Fig. 30-21). This signifies the change from the hypopharynx to the cervical esophagus, and the semilunar-shaped muscle is the cricopharyngeus. Its flatter shape is the result of its attachment to the lateral aspect of the thyroid and cricoid cartilages.

Magnetic Resonance Imaging

Because of motion artifact, the larynx has been difficult to image well with MR imaging. This modality does have the capability of multiplanar high-resolution imaging, and compared with CT, MR imaging has an increased ability to separate various soft tissues such as tumor and muscle.[13, 15–18, 26, 28, 29] However, the multiplanar capabilities of multidetector CT may challenge the abilities of MR imaging to better define lesions.

The actual pulse sequences used by different radiologists vary considerably and certainly will change with the continued evolution of this technology. As with CT, for MR imaging the patient is positioned with the airway as parallel to the tabletop as possible, but the plane of imaging can be angled when the patient is not in a perfect position. Currently, a sagittal T1-weighted localizer series is obtained to identify the axis of the larynx. This sequence ranges from one sternocleidomastoid muscle to the other to include the major lymph node groups.

A coronal T1-weighted series is performed with thin sections (3 to 5 mm), extending from the anterior vocal cords to the posterior larynx, in a plane perpendicular to the cords. An axial thin-section, T1-weighted sequence is then done, covering the larynx from the upper epiglottis to the lower cricoid. The anatomic level is chosen to cover the area of maximum interest (usually the true cord, ventricle, and false cord). Finally, an axial T2-weighted sequence is performed. The long TR allows multiple slices to be obtained, and thus the primary node-bearing areas can be covered. If there is a supraglottic lesion, the region from the midmandible to below the cricoid is imaged. With lower cord or subglottic lesions, the lower neck is evaluated.

Fast spin-echo (FSE) imaging gives excellent images with valuable T2 information. Fat suppression may be used, as the fat signal can be high on FSE images. This allows better appreciation of the higher signal intensity coming from abnormal soft tissues that may be bordered by fat. FSE T1-weighted images are also available (Fig. 30-22).

The use of gadolinium in laryngeal imaging is still controversial. Some feel that by using gadolinium, important information can be obtained regarding the interface of

VIEW IMAGE

tumor with muscle. Often axial contrast-enhanced images are the most useful. However, FSE T2-weighted images may generate very similar information, obviating the need for gadolinium.

Motion artifacts from breathing, swallowing, and even pulsatile flow in the carotid arteries are major problems with MR imaging. In an attempt to eliminate or minimize these artifacts, a number of flow compensation techniques, respiratory and cardiac gating, and presaturation pulses have been tried, with varying results. Phase-encoding gradients are placed in the anteroposterior direction to move flow artifact away from the larynx in the axial images. Patient education is even more important with MR imaging than with CT. The patient is instructed to breathe quietly and to practice doing so without moving the neck. Shallow abdominal rather than chest breathing is encouraged, and the patient is instructed not to swallow or at least to swallow as seldom as possible during the sequence. However, if the patient must swallow, it should be done quickly rather than struggling to suppress the swallow, as struggling itself may cause even more motion artifact. The neck should not be hyperextended because this makes swallowing more difficult. The neck is kept in a more relaxed neutral position.

A surface coil is used as a receiver. Because the coil should move as little as possible, the technologist should take care to separate the coil from the chest wall while maintaining close approximation to the neck.

Sagittal images show the epiglottis, valleculae, and base of the tongue well (Fig. 30-23). The laryngeal surface of the epiglottis can be followed down to the petiole and the anterior commissure. The postcricoid area is seen well, and the arytenoid cartilage often can be visualized perched atop the cricoid cartilage. The preepiglottic fat is clearly seen on T1-weighted images.

The coronal view represents the ideal orientation for evaluation of the upper margin of the true cord (Figs. 30-24 and 30-25). The ventricle may not be seen, because the patient cannot maintain any particular breathing maneuver during the entire time required for the imaging sequence. The TAM represents the bulk of the true cord, and on T1-weighted images it can be seen contrasted against the high signal intensity fat of the false cord immediately above. Although slips of the TAM invariably extend up into

the false cord level of the paraglottic space, these are very thin, and for practical purposes the upper margin of the true vocal cord is considered to be the upper margin of the muscle. Anteriorly, the petiole and the fat of the preepiglottic space are also visible just above the anterior commissure, whereas posteriorly, the arytenoids again are seen on the cricoid. The subglottic region is seen on the same images as the true cord.

The axial images represent slices perpendicular to the inner surface of the thyroid and cricoid cartilage, allowing assessment of cartilaginous erosion. Again, the appearance of the cartilage is quite variable, depending on the degree of ossification. Ossified cartilage with fat in the medullary space has a high signal intensity on T1-weighted sequences. By comparison, the nonossified cartilage tends to be dark on both T1-weighted and T2-weighted sequences. The ossified cartilage cortex is black on MR images.

The cord level can be identified on axial MR imaging in much the same way as it is with CT; the airway is narrow, and there is the low T1-weighted signal intensity of muscle in the cord. By comparison, a T1-weighted image through the false cord level shows the high T1-weighted signal intensity of fat in the paraglottic area.

Ultrasonography, Nuclear Medicine, and Angiography

Ultrasonography has significant limitations in the larynx. The proximity of the larynx to the skin surface allows the use of very high-resolution, high-frequency 5 to 10 mHz probes.[30] However, when ossified, the cartilage reflects most of the sound, thus limiting ultrasonic access to the larynx. The cystic nature of a laryngocele can be determined, and vocal cord mobility can be assessed.[31, 32] Perichondritis or tumor extension through the thyroid cartilage has been evaluated with ultrasound, but most centers use CT or MR imaging in this evaluation.[33]

Some work has been done using endolaryngeal ultrasound to visualize the deeper areas of the larynx during endoscopy.[34, 35] This method allows assessment of deep tissue infiltration as well as cartilage involvement, and more experience with this ultrasound technique may increase its future applicability.

Because the cartilage is not ossified in the pediatric patient, ultrasound can access the inner larynx.[36] Still, acoustic shadowing of the airway limits the ability to evaluate the posterior larynx, especially the cricoid. Mobility of the cords can be assessed, and invasion into the larynx by lesions such as lymphangiomas can be appreciated. Prenatal ultrasound is not compromised by air because the larynx, trachea, and bronchi are filled with fluid.[37] Thus, prenatal ultrasound has been used to predict laryngeal and tracheal atresia.

Nuclear medicine is seldom used specifically for pathologic conditions of the larynx. Increased uptake in inflammatory arthropathies or relapsing polychondritis occasionally has been mentioned in the literature.[38] Metabolic imaging such as positron emission tomography and single photon emission computed tomography are discussed in Chapter 45.

Arteriography can demonstrate the blood supply to the larynx. Although a primary glomus (paraganglioma) tumor or other vascular lesions can be evaluated by arteriography, this is seldom necessary.[39]

SECTION THREE

PATHOLOGIC CONDITIONS

Congenital, inflammatory, neoplastic, and traumatic abnormalities all affect the larynx.[40, 41] Typically, the clinician has a good idea of the basic clinical problem and seeks the radiologist's help to determine the extent of the particular pathology. Because most modern imaging has been directed toward evaluation of neoplasms, this section begins with and emphasizes tumors. The evaluation of congenital, traumatic, and inflammatory lesions then follows. Although some pathologic conditions are not often evaluated by radiology, they are included here for completeness.

SQUAMOUS CELL CARCINOMA

General Considerations

Cancers of the larynx represent about 1% of all cancers diagnosed, and most laryngeal malignancies are squamous cell carcinomas.[42] Though there is no proven cause of laryngeal carcinoma, there are many strong etiologic associations. The most common risk factors for cancer of the larynx are considered to be smoking and alcohol. More than 95% of patients with laryngeal cancer have been found to have been smokers. About 2% of patients with laryngeal papillomas will develop laryngeal cancer, and the percentage of cancers is higher if the onset of the laryngeal papillomas is in the adult. These lesions are associated with human papilloma virus, and this virus has been found in large numbers of laryngeal cancers, with or without papillomas, again indicating an etiologic association. Other potential associations include mouthwash and gastroesophageal reflux, and many of the associated factors may be related or additive. For instance, smoking or drinking may increase reflux, while various other factors may influence the immune system and affect the body's ability to react to a developing cancer.

Because these cancers usually cause the early symptom of hoarsness, and because these are mucosal tumors and the larynx is accessible to direct visualization, the diagnosis is usually known prior to imaging. Very rarely, a squamous cell carcinoma can arise deep enough in the ventricle to avoid detection on indirect mirror examination. However, such lesions are almost always found if formal endoscopy is performed.

The laryngoscopist may be able to obtain all the information needed for treatment planning without imaging. However, the endoscopist is limited in the ability to define the deep extent of a lesion relative to precise landmarks utilized to determine whether the patient is a candidate for a speech conservation operation or radiotherapy. Because a tumor can cross the acceptable limits of a voice conservation operation by growing deeply through the paraglottic space, such tumor spread can go completely undetected by the laryngoscopist. A good approach to imaging of the larynx in the cancer patient is to concentrate on the specific anatomic landmarks that determine surgical planning. These landmarks are stressed in this chapter.

Clinically, tumors are staged by the TNM classification developed by the American Joint Committee on Cancer (AJCC). The AJCC system is now identical to that of the Union Internationale Contre le Cancer (UICC).[43] Although staging is done primarily by visual inspection, cross-sectional imaging is advised for analysis of areas of deeper tumor involvement. The AJCC system is presented in Box 30-1.

Certain points regarding the relationship of radiology and endoscopy must be emphasized. First, whenever possible, CT or MR imaging should be done prior to biopsy. This avoids confusion in differentiating the findings related to the local trauma of the biopsy procedure and the findings reflecting the tumor itself. Usually the diagnosis is strongly suspected by the clinician after mirror examination, and the clinician can help the radiologist best by initially localizating the lesion.

A second important point is that the mucosal surfaces are in the realm of the endoscopist, and the radiologist should not perform CT or MR imaging as a substitute for direct clinical visualization, as small but clinically obvious mucosal lesions may go undetected on these studies. It is impossible to exclude cancer of the larynx based only on imaging.

Voice Conservation Therapy

Voice conservation therapies include partial laryngectomies, radiation therapy, and organ preservation therapies that combine chemotherapy and radiation therapy. All of these treatments allow some preservation of the ability to have unassisted speech.[44–46] The alternative treatment is a total laryngectomy, which only allows assisted speech using either an esophageal voice valve or an external amplifier.

Although voice conservation surgery allows the patient to maintain the capability of speech using the remaining portion of the larynx, the ability of the remaining larynx to maintain a patent airway and protect the airway from

BOX 30-1
*DEFINITION OF TNM**

Primary Tumor (T)

TX Primary tumor cannot be assessed
T0 No evidence of primary tumor
Tis Carcinoma *in situ*

Supraglottis

T1 Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2 Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx
T3 Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, pre-epiglottic tissues, para
glottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
T4a Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
T4b Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Glottis

T1 Tumor limited to vocal cord(s) (may involve anterior or posterior commissure) with normal mobility
T1a Tumor limited to one vocal cord
T1b Tumor involves both vocal cords
T2 Tumor extends to supraglottis and/or subglottis, and/or with impaired vocal cord mobility
T3 Tumor limited to the larynx with vocal cord fixation and/or invades paraglottic space,
and/or minor thyroid cartilage erosion (e.g., inner cortex)
T4a Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
T4b Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Subglottis

T1 Tumor limited to the subglottis
T2 Tumor extends to vocal cord(s) with normal or impaired mobility
T3 Tumor limited to larynx with vocal cord fixation
T4a Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Regional Lymph Nodes (N)

NX Regional lymph nodes cannot be assessed
N0 No regional lymph node metastasis
N1 Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2 Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
N2b Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3 Metastasis in a lymph node, more than 6 cm in greatest dimension

Distant Metastasis (M)

MX Distant metastasis cannot be assessed
M0 No distant metastasis
M1 Distant metastasis

**T*, Primary tumor; *N*, regional lymph nodes; *M*, metastasis.

aspiration may be compromised. Immediately following most voice conservation surgery, the patient will aspirate. However, if the patient has the desire to go through a retraining period, if the hyoid bone is not fixed by scar tissue, and if there is an adequate pulmonary reserve, most often normal swallowing can be achieved. Some patients will not regain a normal swallow. Also, some voice conservation surgery patients will not be able to be decannulated, as a sufficient airway cannot be reestablished in the postoperative larynx.

The classic voice conservation operations are the (horizontal) supraglottic laryngectomy and the vertical hemilaryngectomy. The supraglottic laryngectomy is done for supraglottic carcinoma, whereas the vertical hemilaryngectomy is done for a lesion isolated to the true vocal cord. These procedures are described in the appropriate sections that follow. The anatomic landmarks used to determine the feasibility of each of these standard partial laryngectomies are also emphasized in the sections dealing with tumors of specific areas within the larynx.

Radiation therapy (RT) also has the ability to preserve voice function. The imaging approach for planning RT is similar to that for planning a partial laryngeal resection. In particular, the overall size of the tumor must be noted, as this is an important factor for the radiation therapist because both tumor volume and depth of penetration help predict the treatment outcome.[47, 48] In general, RT is more successful for superficial lesions than it is for deeply invasive tumors. However, because of patient treatment preferences or medical contraindications to surgery, RT is still used in some extensive lesions.

Only recently have studies appeared in the literature correlating imaging findings with RT outcome. Initial results have found higher recurrence rates with larger supraglottic lesions. In one study, volume was not as important in stage T2 true cord lesions, but the patient numbers were small.[49] Castelijns et al. compared recurrence rates with the involvement of cartilage as shown by MR imaging.[50] Higher recurrence rates were seen in patients with cartilage abnormality than in those with normal signal intensity within cartilage. This is an important concept because the outcome was compared directly with an imaging finding without exact histologic verification. The patient numbers in all of these studies are small, making definite conclusions somewhat premature. However, if absolute determinations are to be made, these preliminary studies do provide a rationale for further investigations.

If a tumor does recur after RT, a salvage total laryngectomy can be performed. This treatment sequence does, however, give a slightly lower overall survival than if a total laryngectomy is done at initial diagnosis.

Cartilage Involvement

The laryngeal cartilages should be assessed during the imaging evaluation of any tumor of the larynx. This evaluation is therefore discussed before the specific regions of the larynx are considered. In actual practice, a tumor confined to the supraglottic larynx very rarely invades the cartilage.[51] Cartilage invasion is much more of a problem in tumors of the true cord, subglottis, and hypopharynx.

Tumor invasion of the cricoid or thyroid cartilage is considered a negative predictor for the prognosis of patients treated with RT, and is considered a contraindication to the standard partial laryngeal operations. Thus, for any patient who is being considered for either RT or a conservation-type laryngectomy, cartilage involvement is an important consideration.

The epiglottis is not a crucial factor in planning treatment, as it is a poor barrier to tumor extension and it is routinely removed in a supraglottic laryngectomy without consequence to the patient. Similarly, minimum involvement of the vocal process of the arytenoid does not exclude a partial resection. Some of the more advanced types of partial laryngectomy may include a resection of one of the arytenoid cartilages if it is deemed necessary.

Mineralization of the cartilages is not uniform and is frequently asymmetric. By the age at which most patients develop laryngeal carcinoma, much of both the cricoid cartilage and the thyroid cartilage is ossified. As mentioned, ossification follows the line of attachment of the muscles to these cartilages, and thus the thyroid cartilage usually ossifies from the inferior margin superiorly and from the posterior margin anteriorly. Small islands of both ossified and nonossified cartilage are frequently seen in the broad, flat alar regions of the thyroid cartilage. The cricoid cartilage usually ossifies along the superior edge, the back of the lamina, and then along the upper margin of the cricoid arch. As a result of this partial ossification, the thyroid, the cricoid, and even the arytenoid cartilages may contain cortical bone, fatty marrow, and nonossified cartilage.

On CT, a tumor usually has an attenuation approximating that of nonossified cartilage or muscle (soft-tissue density), and minimal cartilage involvement is almost impossible to identify (Fig. 30-26). Gross cartilage destruction can be seen. The most reliable CT sign of cartilage invasion is the demonstration of through-and-through tumor spread, that is, the visualization of tumor on the opposite side of the cartilage from the primary lesion.[52] Obliteration of the marrow fat as tumor involves the medullary space of ossified cartilage may also be identified on CT.

Cartilage sclerosis seen on CT is a reactive phenomenon and thus does not necessarily mean that actual tumor invasion of the cartilage has occurred (Fig. 30-27). A tumor close to the perichondrium is thought to be able to cause cartilage sclerosis because of the adjacent inflammatory response that is frequently identified at the margin of a squamous cell carcinoma. Although more experience is needed to clarify this relationship, at present cartilage sclerosis is believed to indicate that tumor is either in or at least against the cartilage.

On MR, the most reliable imaging sign is still the demonstration of tumor spread through the cartilage, with tumor on the opposite side of the cartilage from the primary lesion. However, there is evidence that suggests that lesser degrees of tumor involvement may also be detectable with MR imaging, as variations in the signal patterns of normal and abnormal cartilage are seen on different pulse sequences.[29, 53–55]

MR imaging shows the cortex of ossified cartilage as a signal void, while fatty marrow is bright on T1-weighted sequences. Nonossified cartilage has a relatively low T1-weighted signal intensity and also has low signal on T2-weighted images. Although nonossified cartilage does not have as low a signal intensity as cortical bone, it

FIGURE 30-26 Axial CT scans of a transglottic tumor with cartilage destruction. **A**, The level close to the ventricle shows the tumor (*T*). There is definite demineralization of the thyroid ala (*arrowheads*) but no significant thickening of the strap muscles on the outer surface of the thyroid. **B**, Bone algorithm shows the demineralization of the cartilage, which is strongly indicative of tumor invasion. There has been slight buckling (*arrowhead*) of the thyroid ala because of the weakening of the cartilage. The arytenoid (*A*) is sclerotic. **C**, Scan through the cricoid shows tumor within the ring of the cricoid and, at this level, tumor extending outside of the larynx (*arrowheads*). **D**, Bone algorithm showing destruction of the thyroid cartilage (*arrowheads*).

has a much lower signal intensity than the either fat or tumor.

Since tumor has an intermediate signal intensity on T1-weighted sequences, any area that has a high (bright) T1-weighted szignal intensity typical of fat, represents ossified cartilage and can be reliably considered normal. A relatively dark segment of cartilage on T1-weighted images may represent either tumor or nonossified cartilage, and the T2-weighted image is used to help distinguish between these two possibilities (Figs. 30-28 to 30-30).

Tumors such as squamous cell carcinoma tend to have an intermediate or relatively high signal intensity on T2-weighted images, while nonossified cartilage has a lower T2-weighted signal intensity.[29, 53, 54] Thus, differentiation of tumor and nonossified cartilage is possible on T2-weighted images. Occasionally on T2-weighted images, tumor-infiltrated cartilage and uninvolved cartilage may actually

Copyright © 2003, Mosby, Inc. All rights reserved.

look the same, as tumor may have a relatively bright appearance and a fatty medullary area may retain a significant amount of signal because of its proximity to the surface coil. The important imaging finding is the change in appearance that occurs when short and long TR sequences are compared. Intermediate to low signal intensity on T1-weighted images and intermediate to high signal intensity on T2-weighted images suggest the presence of tumor. The use of FSE imaging with fat suppression has not only allowed highly detailed T2-weighted images, but with fat suppression the difference between tumor and the fat-containing medullary space may be accentuated.

Although Castelijns et al. used a midfield strength unit and an earlier echo (because of the diminishing signal on the later echo images), they demonstrated that tumor invasion of cartilage showed relative brightening on T2-weighted images compared with its appearance on T1-weighted images. Again, nonossified cartilage remained dark. Early experience using high field units and later echo times is encouraging, and although more experience is needed for verification, if proven reliable this finding will be diagnostically helpful.

Gadolinium also increases the signal intensity of the tumor. Limited experience using T1-weighted, contrast-enhanced, fat-suppressed images has indicated that one may be able to define early cartilage invasion (Fig. 30-29). However, high-quality T2-weighted FSE images may give the same information as gadolinium-enhanced, fat-suppressed images and therefore obviate the need for the contrast study.

The specificity of the high T2-weighted signal intensity has been questioned because the inflammatory changes that frequently accompany squamous cell carcinoma also give a relatively high T2-weighted signal. High T2-weighted signal intensity also can be present with ''red'' marrow, which may occasionally be found in the thyroid cartilage.[55] Currently, if the cartilage has normal signal (bright on T1), one can feel confident that the cartilage has not been invaded. If the signal is low to intermediate on T1-weighted and high on T2-weighted sequences or if the cartilage enhances, the cartilage is very likely abnormal. If the tumor abuts the questionable area, suspicion increases that the cartilage has been invaded by tumor. At times, one can see variations of signal intensity in the cartilage, suggesting either bulk tumor

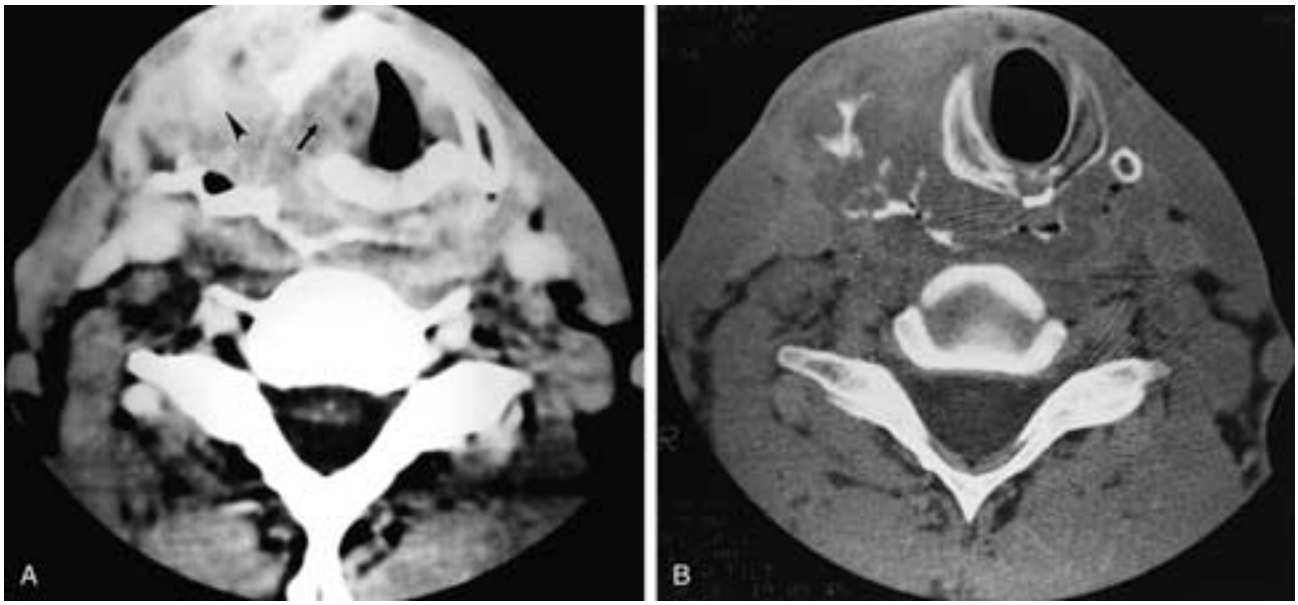

FIGURE 30-27 Axial CT scans show extensive pharyngeal tumor invading the larynx. **A**, Tumor of the pyriform sinus extending into the true cord level (*arrow*) and laterally (*arrowhead*). **B**, Lower level shows marked sclerosis of the cricoid cartilage on the involved side. The uninvolved side is normal. Tumor did not extend into the cartilage. The sclerotic reaction was definitely free of tumor histologically.

or edema (Figs. 30-31 and 30-32). The edema may be brighter on T2 sequences than actual bulk tumor. Again, further evaluation of this differentiation and its significance is warranted.

The significance of the inflammatory response is not known. It is possible that inflammatory edema may carry viable tumor cells. If this is the case, the inflammatory tissue would have to be treated as tumor and included in the resection or in the port of RT. Usually with cases that are questionable, there has been some other factor that tips the decision toward more radical treatment.

At times the tumor may have a relatively low signal intensity on T2-weighted images (Fig. 30-32). In this case, the involved cartilage will be relatively dark on both T1-weighted and T2-weighted images. However, the tumor within the cartilage should not be darker than the non-ossified cartilage and should follow the signal pattern of the tumor in the soft tissues of the larynx. This concept is relatively new, and further work is necessary before a definitive statement can be made regarding the importance of these findings.

Nodal Metastasis

Nodal metastasis is common with supraglottic tumors and rare with glottic tumors, but it should be considered during the assessment of any tumor arising at any site within the larynx.

The clinical presence or pathologic detection of metastatic adenopathy is accompanied by a lowered rate of survival.[56] More ominous is the presence of tumor extension through the capsule of a node (extracapsular spread). Although detection of large nodes by palpation is reliable, palpation fails to identify smaller or deeply situated nodes. Even on imaging, there can be false-positive and false-negative assessments.[57] This topic is discussed in Chapter 36.

Further Workup of the Patient with Squamous Cell Carcinoma

A patient with squamous cell cancer of the larynx, especially of the supraglottic larynx, has a relatively high risk (10% to 20%) of having or developing a second primary malignancy.[58] This may be the result of the common exposure of certain areas to carcinogens such as cigarette smoke or ethanol. The regions most likely to be involved are the oral cavity, larynx, pharynx, lung, esophagus, and, less often, the stomach (Fig. 30-33).

A barium swallow examination can be performed to search for second primary lesions in a patient diagnosed with a squamous cell carcinoma of the larynx. A truly negative barium swallow study is a very reliable test. Any area of mucosal irregularity, diminished pliability, or lack of distention should be evaluated by endoscopy and biopsy.

A chest radiograph is a good survey examination to evaluate for a second primary in the lung or the rare pulmonary metastasis. Some clinicians prefer the higher sensitivity of the chest CT study for the preoperative assessment of patients with head and neck carcinoma.

SITE-SPECIFIC EVALUATION

As stated in the section titled Anatomy, the larynx is subdivided into supraglottic, glottic, and subglottic areas. This classification is based on embryologic derivation, lymphatic drainage of the mucosa, and the clinical behavior of laryngeal tumors. The division is important for surgical statistics, but for the purposes of this chapter, the glottic and subglottic lesions are discussed together. Because of the proximity of the hypopharynx and the pyriform sinuses to the larynx, the discussion of carcinoma in one of these regions necessitates the discussion of carcinoma in the other; therefore, hypopharyngeal carcinoma is covered as well.

Supraglottic Larynx

Because the false cords are not directly used in vocalization, supraglottic tumors do not cause early hoarseness and are discovered somewhat later than are tumors arising in the true vocal cords. Therefore, at the time of diagnosis, supraglottic tumors are usually larger than tumors involving the true cord. Patients with a supraglottic tumor may have a ''hot potato'' voice, but they are not usually hoarse unless there is significant tumor extension onto the arytenoid cartilage or down into the true cord.

The standard voice conservation surgery related to the supraglottic larynx is the supraglottic laryngectomy (see Box 30-2).[59–62] Almost all of the larynx above the ventricle is removed, sparing the arytenoid cartilages if possible (Fig. 30-34). A horizontal cut is made through the upper thyroid cartilage, and the soft-tissue incision line is along the ventricle and just above the anterior commissure. More posteriorly, the incision moves upward over the AE fold just anterior to the arytenoid before passing along the medial wall of the pyriform sinus to complete the resection. The hyoid bone may or may not be removed.

The limits of the tumor are of obvious importance. Imaging is responsible for identifying some pathways of tumor spread more than others, as some tumor extension is

BOX 30-2 CONTRAINDICATIONS TO SUPRAGLOTTIC LARYNGECTOMY

1. Tumor extension onto the cricoid cartilage
2. Bilateral arytenoid involvement
3. Arytenoid fixation
4. Extension onto the glottis or impaired vocal cord mobility
5. Thyroid cartilage invasion
6. Involvement of the apex of the pyriform sinus or postcricoid region
7. Involvement of the base of the tongue more than 1 cm posteriorly to the circumvallate papillae

FIGURE 30-30 Carcinoma of the larynx invading the thyroid cartilage. **A**, Axial CT of the larynx shows a tumor (*T*). On the soft-tissue window the cartilage is unremarkable. Note the nonossified cartilage (*arrowhead*) and the ossified cartilage (*arrow*). **B**, Bone algorithm shows no definite abnormality. Again, both nonossified (*arrowhead*) and ossified (*arrow*) cartilage can be identified. **C**, MR T1-weighted image shows tumor (*T*). The thyroid cartilage (*arrowheads*) on the side of the tumor has intermediate signal, suggesting tumor involvement. On the opposite side there is fat in the medullary cavity of the cartilage (*arrow*). **D**, Axial T2-weighted image with fat suppression shows a definite increase in signal (*arrowheads*) in the involved thyroid cartilage. Note that there is relative sparing of the nonossified portion (*arrow*) of the cartilage.

easily seen endoscopically. By far the most important margin to assess is the inferior border of the tumor. In addition, the degree of spread into the preepiglottic and paraglottic regions relates to the likelihood of nodal metastasis. The supraglottic larynx may be subdivided into the suprahyoid and infrahyoid regions. Many tumors involve both regions, but some are small enough to be localized to only one area.

Suprahyoid lesions include tumors of the free margin of the epiglottis. Small tumors in this area can be resected without removing the entire supraglottic larynx. The hyoepiglottic ligament acts as a barrier to spread of suprahyoid or low tongue base lesions into the preepiglottic space (Fig. 30-35).[4] The management of the base of the tongue is often a clinical problem with suprahyoid cancers, because these lesions tend to extend anteriorly into the tongue (Fig. 30-36). Today many surgeons have expanded the classic criteria for a supraglottic laryngectomy to include lesions that extend less than 2 cm into the tongue base. Unless the lesion is very small, the true size of these lesions is difficult for the endoscopist to appreciate, as the lesion may indeed be the tip of an ''iceberg,'' with tumor extending deeply into the tongue base or the infrahyoid larynx. However, if the lesion extends into the infrahyoid larynx, the laryngeal surface of the epiglottis is usually involved and the extent of an infrahyoid tumor can often be appreciated at endoscopy.

The suprahyoid supraglottic larynx is well seen on axial CT and MR imaging. The lesion can extend laterally along the pharyngoepiglottic folds to reach the pharyngeal wall or along the glossoepiglottic fold in the midline of the floor of the valleculae to reach the tongue base. The extension into the tongue base is best seen on MR imaging, especially on sagittal views (Fig. 30-36).[28] The normal lingual tonsil is situated in the region of the valleculae and, as mentioned, can normally extend down to the anterior vallecular wall. It

VIEW IMAGE

will not extend into the floor or posterior wall of the valleculae, and any such soft tissue must be considered tumor until proven otherwise. Even so, at times it may be impossible to differentiate normal tonsillar tissue from a tumor. Imaging can identify the unusually deep and caudad tumor extension of these suprahyoid epiglottic tumors into the infrahyoid larynx and the preepiglottic fat. These areas are well seen on either CT or MR imaging.

The infrahyoid supraglottic larynx is bordered by the easily visualized AE folds. Lesions at the posterior margin of the AE folds can spill over onto the pharyngeal wall. Lesions arising on the epiglottis usually have anterior extension through the epiglottis into the preepiglottic fat (Fig. 30-37). As mentioned, on gross inspection the cartilage itself is sieve-like, and the epiglottis is a poor barrier to tumor spread into the preepiglottic fat. The fact that the lesion has entered the preepiglottic fat does not preclude a supraglottic laryngectomy, but it does modify the surgical approach because neck metastases are more likely. On imaging, tumor is easily seen infiltrating into the fat density of the preepiglottic space on CT or into the high signal of the fat on T1-weighted MR imaging.

Because the resection line of a supraglottic laryngectomy is through the ventricles, the key to the feasibility of a supraglottic laryngectomy is the inferior tumor extension. Tumor cannot involve the ventricles, arytenoids, or anterior commissure. For the radiologist, the most important of these structures is the ventricle.

Because the slit-like ventricle is in the axial plane, it is poorly seen on axial scans. The ventricle is best visualized in the coronal plane, where it is seen in cross section. Thus, the coronal plane is the best plane to determine the relationship of the lower edge of the tumor to the ventricle.

Since the ventricle itself cannot be well visualized, as previously mentioned there are other anatomic landmarks that can be used to localize the level of the ventricle.

The arytenoid actually spans the ventricle. The upper arytenoid is at the level of the false cord, and the vocal process is at the level of the true cord. Also, the false cord is composed predominantly of fat, whereas the cord level is marked by the TAM. Thus, the soft tissue change from fat to muscle density marks the transition across the ventricle.

If the supraglottic laryngectomy is feasible, the radiologist should be able to show an axial image without tumor between the caudal margin of the tumor and the upper margin of the normal true cord (Fig. 30-38). On the other hand, if the lesion is seen both above and below the ventricle, it is trans-

VIEW IMAGE

glottic (crosses the ventricle), and a supraglottic resection is not possible (Figs. 30-32, 30-39 and 30-40).

The greatest diagnostic challenge relates to those cases in which the tumor is very close to the ventricle. Definition of the inferior tumor boundary in these cases can be very difficult (Fig. 30-37). Tumor can cross the ventricle by growing along the mucosa either anterior to or posterior to the ventricle. Invasive supraglottic lesions can grow through the quadrangular membrane into the paraglottic space and then around the lateral margin of the ventricle to invade the outer margin of the true cord[63] (Fig. 30-41). This pathway is controversial, as some authors doubt that isolated paraglottic spread occurs without coexistent mucosal transglottic spread.[51, 64, 65]

As previously mentioned, some authors believe that the paraglottic space is at least partially compartmented and that the fascial layers that define the compartments could represent potential barriers to paraglottic tumor spread.[7] The thyroglottic ligament curves from the thyroid cartilage inward to the vocal ligament (see Fig. 30-7) and is considered by some authors as the boundary of the paraglottic space.[5] However, most authors consider the paraglottic space as bounded medially by the quadrangular membrane and the relatively thin thyroglottic ligament as a structure predominantly within the paraglottic space.

If there is enough tumor growth to actually invade the TAM, cord motion becomes limited. With more tumor invasion, the cord becomes fixed and the invasion can be clinically identified. However, more limited invasion can theoretically cross the ventricle without causing cord fixation, and such disease is best detected at imaging. In order to assess such tumor spread, the superolateral margin of the TAM becomes a key imaging landmark.

The coronal plane shows a perfect cross section of the ventricle and the thyroarytenoid muscle. Normally, there is a small amount of fat that can be seen ''tucking'' into the upper outer margin of the TAM (Fig. 30-42). The invading tumor will obliterate this fat and eventually will appear to ''pry'' the muscle away from the thyroid cartilage (Fig. 30-42). If this fat is seen intact, it is good evidence that the tumor has not crossed into the cord.

As previously noted, in the axial plane the ventricle is localized by the transition from the fat of the supraglottic larynx to the muscle of the glottic level. If thin scans are used, the small ''crease'' of fat at the upper outer margin of the TAM may be identified. Tumor infiltration is seen as it pries its way into this level (Figs. 30-42 to 30-44). This is best appreciated on MR imaging because the difference between the appearance of muscle and tumor is more definitive than on CT (Fig. 30-45). On CT, tumor has approximately the same attenuation as muscle. On T1-weighted MR imaging, tumor and muscle may also have similar signal intensity. However, on T2-weighted images, tumor usually has a relatively higher signal intensity than

Copyright © 2003, Mosby, Inc. All rights reserved.

does normal muscle. Tumor also tends to enhance more than muscle after the administration of gadolinium, and these factors are useful in evaluating tumor invasion of the upper margin of the TAM. Thus, relative brightening of the muscle may indicate tumor invasion, but caution must be exercised, as inflammation will also cause such brightening (Figs. 30-41 and 30-46).

As stated previously, squamous cell carcinoma can be associated with an inflammatory response along the margin of the tumor, and this gives a high signal intensity on T2-weighted images. Thus, abnormal signal may extend beyond the actual limit of the tumor. The significance of the inflammatory response is unknown. Some believe that it may be a protective effect, signaling a better therapeutic response. However, it is currently not known whether the inflamed area should be treated as tumor. In general, it is very likely that a muscle of normal signal intensity is uninvolved, and one that is bright on T2-weighted images and/or enhances must be considered abnormal.

Since the thin fat line along the lateral aspect of the TAM is not obvious in all patients, its lack of visualization does not necessarily mean that tumor is present. It may be due either to the phase of respiration or simply to a relative lack of fat at that level.

An epiglottic tumor in the midline tends to extend down along the laryngeal surface of the epiglottis toward the

FIGURE 30-39 *Continued.* **E**, Sagittal reformat shows the tumor (*black arrowheads*) pushing forward, limited by the thyrohyoid membrane. This image is just off the midline at the level of the cricoarytenoid joint (*arrow*). There is destruction of the epiglottis, with tumor (*white arrowhead*) extending into the tongue base. The hyoepiglottic membrane (ligament) is destroyed. **F**, Sagittal image of the lateral neck shows several metastatic nodes.

anterior commissure rather than the ventricle (Figs. 30-47 and 30-48). If a standard supraglottic laryngectomy is to be performed for a midline lesion, there should be a 2 to 3 mm separation between the caudal margin of the tumor and the anterior commissure. When assessing this region on axial scans, the radiologist must be very careful to make the scan parallel to the ventricle. If this is not accomplished, the lower supraglottic larynx is usually seen anteriorly at the same level as the posterior commissure, giving the false impression that tumor may be present in the anterior commisssure. This altered oblique scan plane occurs most often because the patient's head is propped up slightly for comfort, bringing the plane of the larynx out of the plane of the tabletop.

On MR imaging, the fat on either side of the petiole can be seen, and on a sagittal image the integrity of the fat anteriorly, and the presence of air against the lower epiglottis, are relatively reliable signs that tumor has not extended to the anterior commissure. If the anterior true or false cords press against each other, a partial volume artifact can result and can give the false-positive impression that tumor has reached the anterior commissure. Because of this, the presence of air in this region is a more reliable negative sign than is the presence of soft tissue a positive sign of tumor presence.

In the posterior supraglottic larynx, the arytenoids are almost always assessed by direct visualization. If the upper level of one arytenoid is minimally involved by tumor, this arytenoid can be removed surgically. However, involvement of the interarytenoid area is considered a contraindication to supraglottic resection because the surgeon would have to remove both arytenoids to attain a clear margin, and the patient would have no true cords with which to generate a voice. Thus primary lesions of the interarytenoid area, even though small, are almost always treated by total laryngectomy if surgery is the treatment of choice (Figs. 30-49 and 30-50). The interarytenoid region is not usually a diagnostic concern for the radiologist because this area is very clearly seen at endoscopy.

Involvement of the thyroid cartilage is also a contraindication to supraglottic resection. This topic is discussed earlier in this chapter. However, it is extremely unusual for a supraglottic tumor to involve the cartilage unless the tumor has crossed the ventricle.

Lymph node involvement is common in supraglottic carcinoma. Nodal involvement is most common in lesions involving the AE fold and epiglottis that also involve the contiguous tongue and pharynx.[56] The incidence of nodal disease gradually diminishes with tumors that involve the margins of the larynx without contiguous spread and is lowest with small tumors that are isolated to the more central supraglottic larynx. Deeper tumor extension into the preepiglottic and paraglottic spaces is also generally associated with a higher incidence of lymph node metastasis.

The lymphatic drainage of the supraglottic larynx is to the upper jugular chain (levels II and III), and bilateral nodal involvement is common, especially if the lesion crosses the midline.[66] If the entire neck is not routinely scanned on CT, at least these upper nodes must be imaged. With MR imaging, coronal or sagittal imaging also visualizes these nodes.

Other procedures have been devised for supraglottic tumors that are considered as alternatives to, or extensions of, the classical supraglottic laryngectomy.

The near-total laryngectomy described by Pearson et al. resects one hemilarynx and continues down to resect the cricoid on the ipsilateral side.[67, 68] The pyriform sinus is taken on the same side. This operation is performed for supraglottic tumors extending to the true cord on one side or for an AE fold tumor extending into the pyriform sinus. One innervated cord remains, and a flap from the pharynx is used to reconstruct an air passage. If the cricoid is taken, the

airway is unsupported and a tracheostomy must remain to ensure an adequate airway. However, the patient can speak through the reconstructed larynx.

The supracricoid partial laryngectomy with cricohyoidopexy removes not only the supraglottic larynx, but significant parts of the anterior true cords as well (see Fig. 30-141).[69] Ideally, both arytenoid cartilages remain; however, one may be resected if the tumor reaches the vocal process. The cricoid cartilage is left intact, and is pulled up and attached to the hyoid. This procedure is done for supraglottic lesions with extension to the cords. It can be done even with early cartilage invasion. As with true cord lesions, tumor reaching the cricoid cartilage is considered a contraindication, as is extensive cartilage invasion with tumor reaching the outer perichondrium of the thyroid cartilage. Hyoid invasion is a contraindication as well.

FIGURE 30-43 Supraglottic laryngectomy leaving tumor that was unsuspected passing along the paraglottic space. The mucosa of the true cords (*arrow*) is normal. A small amount of tumor (*arrowhead*) has been left because the incision was taken through the ventricle. Compare with Figure 30-40B. Note the characteristic cut through the thyroid cartilage performed as part of the supraglottic resection. (Courtesy of Dr. James Boyd.)

Endoscopic laser resection obviates the external incision.[70] The laser is used to excise rather than vaporize the lesion. Laser resection is easiest to perform for lesions that are readily visualized by the endoscope. The most amenable lesions arise at the false cord level, on the epiglottis, or on the AE fold. Tumors higher on the endolaryngeal surface of the epiglottis and the upper false cord are more difficult to see and therefore to excise by this technique.

Glottic and Infraglottic Regions

The region of the larynx inferior to the ventricle is divided into the glottic and subglottic or infraglottic levels. The boundary between the two regions is a plane parallel to, but 1 cm caudal to, an axial plane passing through the apex of each ventricle. Almost all tumors that occur in this region are squamous cell carcinomas. Unlike supraglottic lesions, tumors of the true cord usually present at a fairly early stage because they interfere with normal vocalization. Even very small lesions of the true cord will cause hoarseness. If the subglottic larynx is involved by tumor and the free margin of the true cord is uninvolved, the patient may not have hoarseness. Fortunately, these lesions are rare.

Many small true cord lesions are treated by RT, cord stripping, or laser resection.[71] The standard speech conservation partial laryngectomy applicable to this region is the vertical hemilaryngectomy.[60, 72, 73] The resection removes one false cord, one true cord, and the intervening ventricle, as well as most of the ipsilateral thyroid ala (Fig. 30-51). The outer perichondrium of the thyroid ala is retained. If the tumor is close to or minimally involves the vocal process of the arytenoid, this process can be resected, leaving most of the arytenoid. However, slightly greater involvement necessitates removal of the arytenoid. If there is deep tumor extension, especially involving the cricoarytenoid joint, the procedure is not performed. Similarly, if the lesion is deeply invasive, with total fixation of a cord, a vertical hemilaryngectomy is not done. Significant cartilage invasion is also considered a contraindication to this procedure.

With a glottic tumor, the key points for assessment are the inferior tumor extension, the anterior commissure, the arytenoid, the thyroid cartilage, and the paraglottic space at the level of the ventricle (Box 30-3). Although nodes are less of a problem than they are with supraglottic carcinoma, they should be sought, especially in the paratracheal and lower jugular areas (levels IV and VI). True cord tumors invading the paraglottic space can metastasize to the upper jugular nodes as well.

The most important consideration is the inferior extent of tumor. If the lesion reaches the upper margin of the cricoid, a routine vertical hemilaryngectomy cannot be done (Fig. 30-52). Some surgeons have resected the upper margin of the cartilage, and work is being done on near-total

laryngectomies. However, the cricoid is the structural foundation of the larynx, and reconstruction of a usable larynx after partial removal of the cricoid is difficult. If the cricoid is involved with tumor, a total laryngectomy is usually performed.

The conus elasticus is thought to play an important role relating to the inferior growth of a true cord tumor (Fig. 30-7). This membrane represents the lower boundary of the paraglottic space and extends from the free edge of the true vocal cord to the upper margin of the cricoid cartilage. The membrane affects tumor extension in two situations. A mucosal true cord tumor that has grown caudally is separated from the deeper soft tissues and cartilage by the thick, ligamentous conus. However, caudal to the conus, a tumor invading the mucosa can immediately invade the cricoid cartilage. Alternatively, if a tumor has extended deep to the mucosa into the true cord and then grows caudally, the conus elasticus becomes a barrier to inferior growth and directs the tumor laterally. Although there may be no detectable subglottic mucosal tumor, the tumor may grow between the cricoid and thyroid cartilages into the extralaryngeal soft tissues.

The key imaging concept is the demonstration of whether or not the tumor has reached the upper margin of the cricoid cartilage. Such inferior extension is easily assessed on axial or coronal scans (Figs. 30-53 to 30-55).

Because of the cricoid's shape, the extent of tolerable inferior growth varies from anterior to posterior. Anteriorly, 1 cm of inferior extension is acceptable. More posteriorly, only 0.5 cm is allowed before the cartilage margin is reached. The cartilage is easily recognizable on axial scans, and if the lesion extends ''into the ring,'' a total laryngectomy is usually necessary if surgery is the chosen treatment. The cricoid also is easily identified on coronal

Copyright © 2003, Mosby, Inc. All rights reserved.

imaging, and tumor extending along its inner cortex is an ominous sign.

Although inferior tumor extension is the most important information sought by the radiologist, other findings also can alter surgical planning. The true vocal cords converge anteriorly, reaching the thyroid cartilage at the anterior commissure. At this midline point, the mucosa separating the airway and the thyroid cartilage is very thin, and a lesion can easily involve the cartilage early in the course of the disease. As mentioned previously, if air is seen against the inner lamina of the thyroid cartilage, tumor is unlikely. The finding of ''tissue'' against the cartilage is a less reliable finding because the cords may come together either physiologically or as a result of edema, obliterating the airway.

Even if the lesion crosses the anterior commissure, an extended vertical hemilaryngectomy may be done as long as the posterior half of one true cord is free of tumor and the cartilage is not eroded. The surgeon alters the cut through the thyroid cartilage, depending on the segment of the opposite cord that must be resected.

Superficial tumor extension along the cord or across the anterior commissure is best evaluated by direct clinical visualization. Some estimate of this disease can be made on imaging. However, if this tumor mapping is crucial in deciding the feasibility of voice-sparing surgery, confirmation by direct inspection is necessary even though the anterior commissure may at times be difficult to visualize directly.

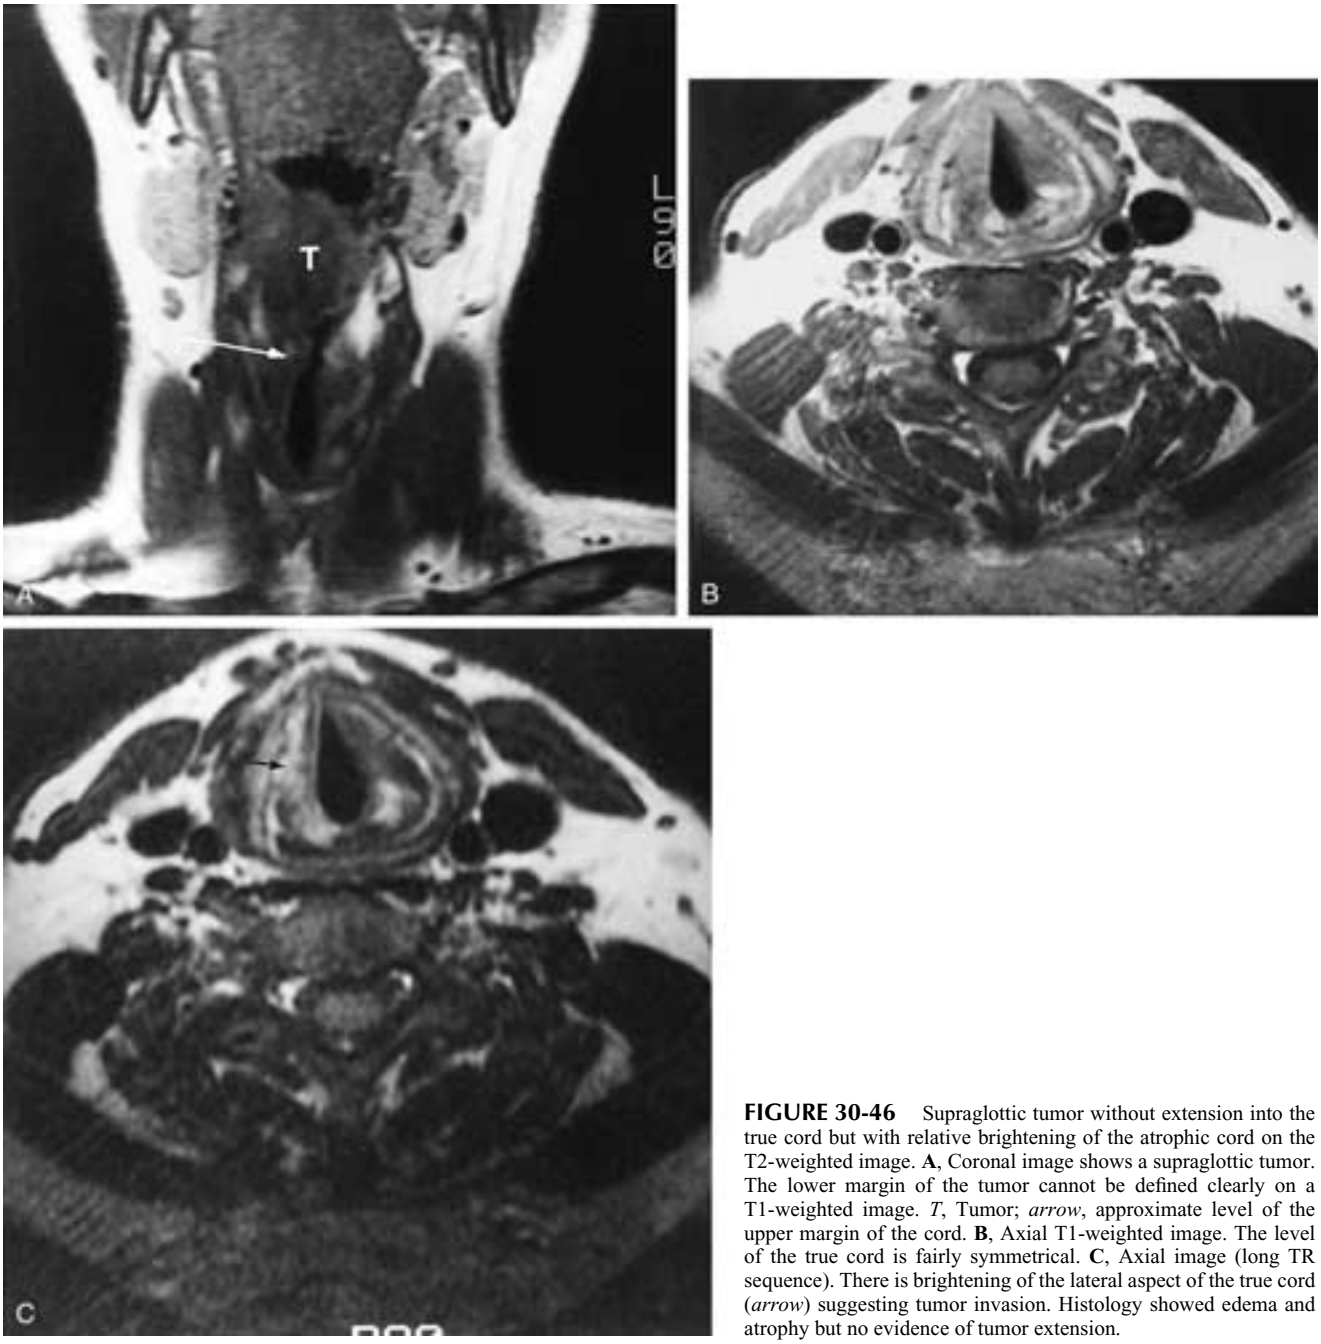

FIGURE 30-46 Supraglottic tumor without extension into the true cord but with relative brightening of the atrophic cord on the T2-weighted image. **A**, Coronal image shows a supraglottic tumor. The lower margin of the tumor cannot be defined clearly on a T1-weighted image. *T*, Tumor; *arrow*, approximate level of the upper margin of the cord. **B**, Axial T1-weighted image. The level of the true cord is fairly symmetrical. **C**, Axial image (long TR sequence). There is brightening of the lateral aspect of the true cord (*arrow*) suggesting tumor invasion. Histology showed edema and atrophy but no evidence of tumor extension.

FIGURE 30-47 Axial CT scans. **A**, Supraglottic tumor extending to the anterior commissure. Supraglottic tumor (*T*) crosses the midline and involves both AE folds (*arrowheads*). **B**, More inferior scan at the level of the true cord shows involvement of the anterior commissure (*arrow*).

Particularly in the region of the anterior commissure, the radiologist's attention should be directed toward a search for deep tumor extension. Cartilage invasion may be assessed by CT or MR imaging, as previously discussed, and the demonstration of tumor anterior to the cartilage at this point is reliable evidence of cartilage invasion. Anterior tumor often grows through the cricothyroid membrane, just below the inferior margin of the thyroid cartilage (Fig. 30-56). In some cases, both the thyroid cartilage and the cricothyroid membrane are involved. This anterior extension can be undetectable on clinical examination.

The area just anterior to the cricothyroid membrane contains the so-called Delphian node. Lymphatic extension from the anterior commissure region and the subglottis to this node has been described.[74] However, a mass presenting in this position is usually the result of direct tumor extension through the cricothyroid membrane from a primary lesion in the anterior commissure and subglottis (Fig. 30-57).

If a vertical hemilaryngectomy is to be performed, the tumor cannot involve an entire arytenoid cartilage. However, as previously discussed, involvement of the vocal

process is not a contraindication. If a large portion of the arytenoid is involved, the lesion will touch or be in close proximity to the cricoid cartilage, and a standard resection cannot be performed.

The degree of arytenoid involvement is usually assessed by endoscopy. However, deep extension to the region of the cricoarytenoid joint may be submucosal and thus is best established by CT or MR imaging.

Superior extension of a glottic tumor brings the tumor into the false cord (Fig. 30-58). Currently, significant extension to the false cord prohibits a vertical hemilaryngectomy. Tumors arising from the superior surface of the cord are in the ventricle and can spread directly into the paraglottic space. Unlike the regions above or below the ventricle, there is no fibrous barrier to limit lateral growth, and these tumors can grow upward into the paraglottic fat or downward into the TAM, eventually reaching the conus elasticus. From there the lesion may be directed anterolaterally through the defect or hiatus in the cricothyroid membrane.

More extended partial laryngectomies have been devised to treat tumors that have transgressed some of the boundaries allowed for the standard vertical laryngectomy.

The supracricoid partial laryngectomy with cricoidhy-

oidoepiglottopexy is done for true cord lesions with limited extension above the ventricle to the lower supraglottic larynx. This is similar to the supracricoid partial laryngectomy with cricodhyoidopexy described in the section titled Supraglottic Larynx. A portion of the epiglottis is maintained and sutured to the cricoid.

Ventricular Tumors

Squamous cell carcinoma can arise in the ventricle itself. These lesions may arise from the inferior surface of the false cord or from the superior surface of the true cord. Thus, technically they can be either supraglottic or glottic in origin. These lesions may be deep enough in the ventricle that they cannot be directly visualized. Clinically, extension to the true cord can cause hoarseness, while superior tumor extension into the supraglottic paraglottic fat (Fig. 30-59) appears to follow the ventricular appendix and may cause a bulge in the supraglottic larynx suggesting a submucosal lesion.

BOX 30-3 CONTRAINDICATIONS TO VERTICAL FRONTOLATERAL HEMILARYNGECTOMY

1. Tumor extension from the ipsilateral vocal cord across the anterior commissure to involve more than one third of the contralateral vocal cord.
2. Extension subglottically more than 10 mm anteriorly and more than 5 mm posterolaterally.
3. This technique can still be used if the vocal process and anterior surface of the arytenoid are involved, but involvement of the cricoarytenoid joint, interarytenoid area, opposite arytenoid, or rostrum of the cricoid is a contraindication.
4. Extension across the ventricle to the false cord.
5. Thyroid cartilage invasion.
6. Impaired vocal cord mobility is a relative contraindication.

From Lawson W, Biller HF, Suen JY. Cancer of the larynx. In: Suen JY, Myers E, eds. Cancer of the Head and Neck. New York: Churchill Livingstone, 1989;533-591.

Pharynx

The lower pharynx (hypopharynx, laryngopharynx) has roughly the shape of a rectangular solid into whose anterior wall projects the supraglottic larynx. As a result, the lateral and posterior hypopharyngeal walls are rather simple in form, while the anterior wall is more complex. The postcricoid larynx bulges into the lower hypopharynx, the pyriform sinuses project forward on either side of the larynx, and the posterior aspect of the supraglottic larynx projects up into the midportion of the pharynx. The superior limit of the hypopharynx is the hyoid bone or valleculae, and the inferior margin is the lower edge of the cricopharyngeus, where the pharynx meets the esophagus.

The pyriform sinus invaginates between the thyroid cartilage and the AE fold. As such, the paraglottic space of the larynx is just anterior to the pyriform sinus mucosa. A lesion of the anterior wall of the pyriform sinus extending through the mucosa involves the paraglottic space at the level of the false cord (Fig. 30-60). On CT or MR imaging the lesion can be seen extending between the thyroid and arytenoid cartilages through the ‘‘thyroarytenoid gap.’’ The tumor may then extend further inferiorly into the vocal cord via the paraglottic pathway. Primary tumors of the lower false cord and ventricle can extend through the thyroarytenoid gap toward the pharyngeal mucosa, but they usually do not ulcerate this mucosa.

The apex of the pyriform sinus extends deeply into the thyroarytenoid gap and thus is very close to the cricoid cartilage. As a result, lesions of the pyriform apex usually require a total laryngectomy for complete resection. If a lesion is confined to the upper lateral aspect of the AE fold or the upper pyriform sinus, a partial pharyngectomy can be done in combination with a supraglottic laryngectomy (Fig. 30-61). Pearson et al.’s near-total laryngectomy (see above)

Copyright © 2003, Mosby, Inc. All rights reserved.

has also been applied to tumors of the AE fold extending into the pyriform apex.

Tumor extending into the pyriform apex can be visualized on axial CT or MR imaging as obliteration of the fat within or as widening of the thyroarytenoid gap (Figs. 30-60, 30-62). Today, most radiologists prefer to use either CT or MR imaging to determine the inferior tumor margin, and with the high-resolution scans now available, the extent of mucosal tumor can be defined at the same time that the deeper tumor extension is mapped. Alternatively, a pharyngogram can be done with thicker barium that will coat the mucosal surfaces of the hypopharynx and help define the margins of a pyriform sinus lesion. During this procedure, the patient performs a modified Valsalva maneuver to distend the pyriform sinus apex.

The postcricoid region is the lower anterior portion of the hypopharynx at the level of the posterior cricoid lamina. A pharyngeal lesion in this location usually necessitates a total laryngectomy because the resection must include the cricoid cartilage. Once a tumor is established in this area, the primary surgical concern becomes the lower extent of the lesion relative to the cricopharyngeus. Definition of this lower tumor margin helps the clinician decide whether the surgical resection involves only the pharynx or whether the resection must include the cervical esophagus with a reconstruction such as a jejunal interposition.

As previously mentioned, on axial CT or MR imaging, the level of the cricopharyngeus muscle is approximated by the lower margin of the cricoid cartilage (Fig. 30-21). Alternatively, the cricopharyngeus muscle can be identified as a semilunar-shaped muscle along the lower aspect of the cricoid cartilage lamina. Immediately caudal, the cervical esophagus is seen, with an ovoid or circular cross-sectional shape. The transition between these two shapes defines the esophagopharyngeal junction. Thus, this important transition zone usually can be identified at imaging. Lack of esophageal involvement by a tumor is suggested on axial images if the thickness of the pharyngeal wall at the lower margin of the cricoid cartilage returns to normal. However, minimum submucosal tumor spread into the esophagus will go undetected on these images, and often biopsy is the only way to accurately determine the caudal tumor extent. Sagittal MR images may also occasionally be helpful, with visualization of the lower tumor margin (Fig. 30-63).

The lower tumor margin also can be defined on a barium swallow. The cricopharyngeus muscle is almost always identified as a smooth posterior indentation into the barium column, so its relationship to the advancing edge of the tumor can be assessed.

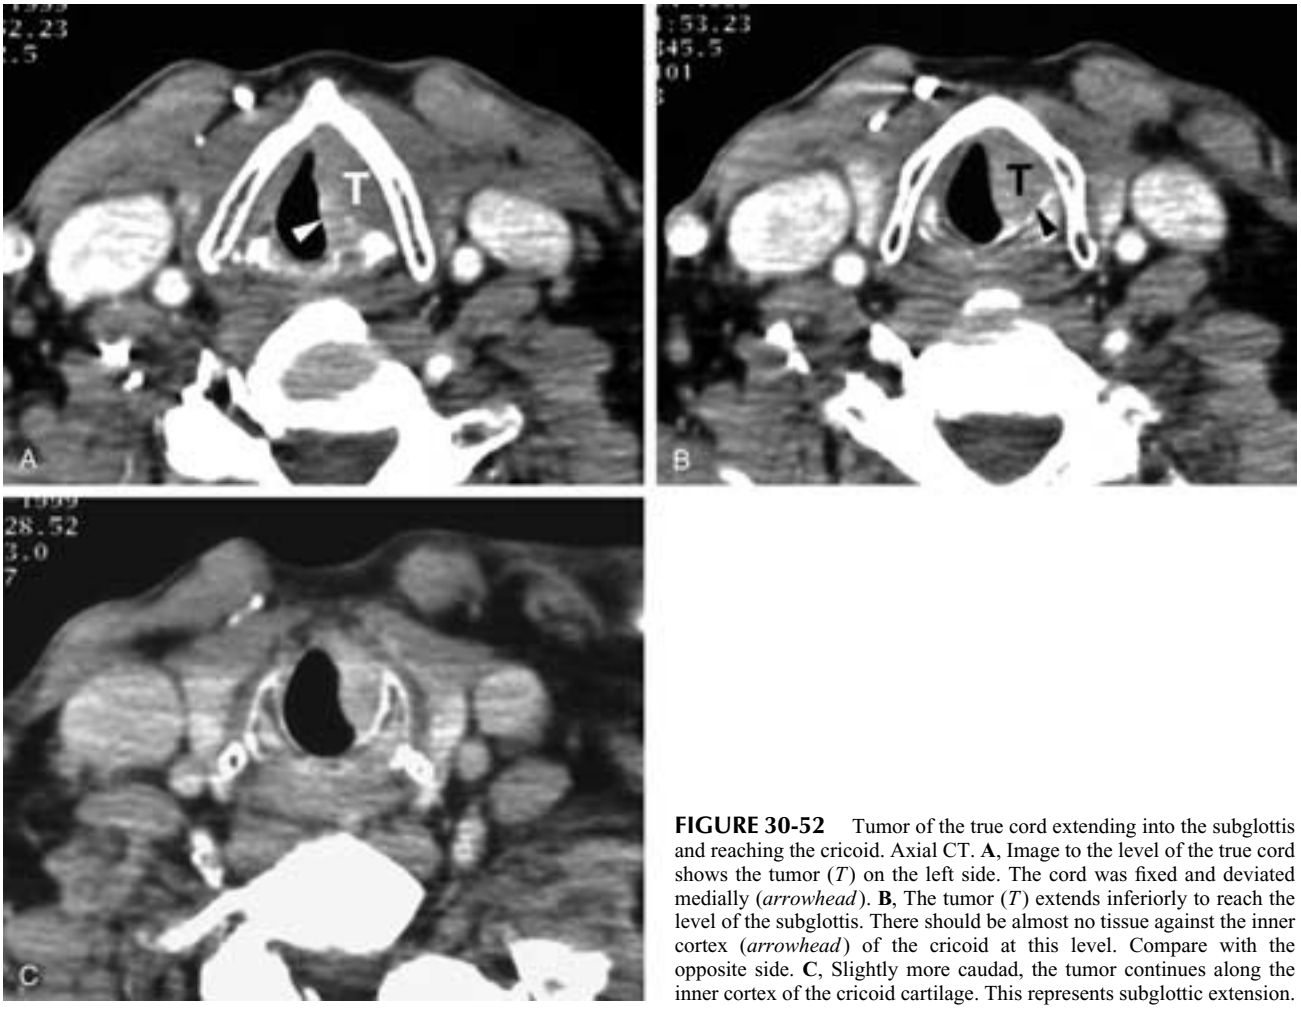

FIGURE 30-52 Tumor of the true cord extending into the subglottis and reaching the cricoid. Axial CT. **A**, Image to the level of the true cord shows the tumor (*T*) on the left side. The cord was fixed and deviated medially (*arrowhead*). **B**, The tumor (*T*) extends inferiorly to reach the level of the subglottis. FIGURE 30-53 Axial CT scans show a predominantly glottic tumor, with extension into the false cord and subglottic extension. **A**, Supraglottic level shows tumor (*T*) with involvement of the anterior surface of the upper arytenoid (*arrowheads*). **B**, Lower scan shows the tumor at approximately the level of the ventricle. **C**, Inferior scan through the level of the cricoid shows tumor (*T*) within the ring. *C*, Cricoid. **D**, Bone algorithm shows loss of the cortical margin of the inner surface of the cricoid (*arrows*).

The actual mucosal surface in the postcricoid region can be difficult to evaluate on barium swallow because of the normal irregularity of the anterior wall that occurs secondary to mucosal redundancy or perhaps a prominent submucosal venous plexus. The pliability of the anterior wall of the postcricoid area is more difficult to assess than the pliability of the lateral or posterior pharyngeal walls because of the rigid support of the cricoid lamina. In addition, this area is relatively ''blind'' to the endoscopist, as the endoscope ''pops'' through the muscular ring into the cervical esophagus and so does not afford the clinician a good view of this important area. Thus, this region should be closely scrutinized by both radiologist and clinician, as failure to identify tumor spread into the esophagus can be disastrous for the patient.

The inferior pharyngeal constrictor muscles act as a relative barrier to lateral and posterior tumor spread. These muscles attach to the lateral aspect of the thyroid cartilage rather than the posterior edge of the thyroid ala. This configuration allows a tumor to ''wrap around'' the posterior margin of the thyroid cartilage along the outer surface of the cartilage, and this extension may occur before there is actual erosion of the cartilage (Fig. 30-60).

Direct lateral tumor extension from the lateral wall of the hypopharynx brings the tumor to the carotid artery, and any involvement of this artery is an important and ominous finding.[75] Neither CT nor MR imaging nor ultrasound has proven reliable in identifying tumor fixation to the arterial adventitia, and the best the radiologist can do is to report the degree to which the tumor encircles the artery.

Direct posterior tumor extension involves the posterior pharyngeal wall and brings the tumor to the prevertebral fascia and muscles. Fixation of this fascia or invasion of the prevertebral muscles worsens the prognosis and limits surgical resectability. If the lesion is ulcerative, fascial invasion is more likely; however, if the tumor is predominantly exophytic, the fascia may not be involved. This can be assessed on lateral fluoroscopy during a barium swallow, because a lesion not fixed to the fascia can slide up and down, relative to the spine, as the barium passes (Fig. 30-64). On MR imaging, a high T2-weighted signal intensity or enhancement after gadolinium administration in the longus colli muscles must be considered abnormal.[76] However, inflammation in these muscles also can have these MR findings. Thus, both false-positive and false-negative results have been reported.

Lymphatic spread from pharyngeal lesions initially reaches the high jugular nodes (levels II and III). Occasionally, a lesion arising in the lower pharynx can also spread superiorly to the high lateral retropharyngeal nodes (nodes of Rouviere) immediately beneath the skull base.

OTHER MALIGNANT TUMORS

Squamous cell carcinoma accounts for 95% of the malignancies of the larynx; however, other benign and malignant lesions do occur.[40, 41] Although the pathologic diagnosis is still made by endoscopy and biopsy, the radiologist may be able to direct the clinician toward a diagnosis other than typical squamous cell carcinoma.[77, 78] This is especially true when the lesion is completely submucosal.

Other carcinomas arising in the larynx include adenocarcinoma (1%), arising in the minor salivary glands, verrucous carcinoma, anaplastic carcinoma, and spindle cell carcinoma.[41]

Adenocarcinoma has the same subtypes as salivary gland neoplasms elsewhere in the body. Adenoid cystic carcinoma is slightly more common in the subglottic larynx, and mucoepidermoid and adenocarcinoma (not otherwise specified) are more common in the supraglottic larynx. Other subtypes of adenocarcinomas are rare.

Verrucous carcinoma is a primarily exophytic tumor. The lesion is wart-like and not very invasive. This tumor almost never metastasizes. Its appearance at endoscopy is very characteristic.

Anaplastic carcinoma, similar to oat cell carcinoma in the lung, is another rare carcinoma of the larynx. The prognosis is poor.

Spindle cell carcinoma is a rare lesion containing elements of a squamous cell carcinoma combined with a spindle cell stroma. There is a difference of opinion as to whether this is a peculiar kind of squamous cell carcinoma or a combination of squamous cell carcinoma and sarcoma.[79] Either or both components can metastasize. Other names for this lesion occasionally found in the literature include pseudosarcoma, carcinosarcoma, pleomorphic carcinoma, polypoid sarcoma, and pseudosarcomatous squamous cell carcinoma. The basic controversy depends on definition of the cell of derivation and the potential of the spindle cell stroma. Does the spindle cell develop directly from the squamous cell as a dedifferentiation toward the mesenchymal form? Is the spindle cell truly of a separate mesenchymal origin? One theory holds that the spindle cell stroma is a reactive phenomenon rather than a true sarcoma.

Any type of sarcoma can be found in the larynx.[80] As a group, sarcomas make up only 0.3% to 1% of all laryngeal malignancies. Although in rare cases they can be large or fungating, they are primarily submucosal. Other than chondrosarcoma, the masses are somewhat nonspecific at imaging, but a smooth mucosal covering should direct the radiologist away from a diagnosis of squamous cell carcinoma.

Special mention should be made of chondrosarcoma because the calcifications (often ring-like) can indicate a specific radiographic diagnosis. These calcifications may be suggested on MR imaging but are more obvious on CT (Figs. 30-65 and 30-66). Usually the origin of the lesion in the cartilage is easily identified by an obvious expansile defect in either the cricoid or the thyroid cartilage (Fig. 30-67). This pattern of cartilage abnormality usually is easily differentiated from the destruction associated with squamous cell carcinoma.

Separation of benign from malignant chondroid lesions is usually impossible based on imaging characteristics. However, most of these tumors behave in a low-grade manner. Even after histologic examination of the entire specimen, differentiation of benign and malignant tumors can be

VIEW IMAGE

difficult. Despite its fairly good prognosis, if a low-grade tumor has extensive cricoid involvement, a total laryngectomy may be considered. Rarely, chondroid lesions can arise from the cricoarytenoid joint (Fig. 30-68).

Chondrosarcoma tends to grow slowly; however, rarely, a secondary more malignant component can develop. This phenomenon is called a dedifferentiated chondrosarcoma (Fig. 30-69). A soft-tissue component appears to arise from the original chondroid lesion and grows rapidly. The soft-tissue component is usually a fibrosarcoma or a malignant fibrous histiocytoma.[81] Osteosarcoma and rhabdosarcoma elements, though less common, have also been described. The prognosis is extremely poor.

Rare primary and metastatic melanomas have been found in the supraglottic larynx and the true cord.[41] Other rare primary tumors involving the larynx include lymphoma, plasmacytoma, fibrous histiocytoma, and Kaposi's sarcoma (Fig. 30-70).[82]

Secondary involvement of the larynx by other than direct tumor extension is rare.[41, 83] Rare metastases from melanomas, renal cell, breast, and lung cancers as well as other rare primaries have been reported, as has involvement by leukemia and lymphoma.[84] No characteristic imaging appearances have been described. Metastasis can be to the soft tissues or can result in an expansile lesion of the cartilage.

BENIGN TUMORS

Benign lesions of the larynx include vocal cord nodules, juvenile papillomatosis, and a variety of nonepithelial tumors.

Copyright © 2003, Mosby, Inc. All rights reserved.

Vocal cord nodules (nonneoplastic, polyps) represent a stromal reaction that occurs in patients with a history of vocal abuse. Clinically, there may be a small fibrotic area on the cord or a more nodular, slightly vascular irregularity. The nodules may be an incidental imaging finding, but they usually are clinically diagnosed, with imaging considered unnecessary (Fig. 30-71). Vocal cord nodules occur on the free margin of the true vocal cord.

Papillomas, although benign and noninvasive, tend to recur after therapy. The wart-like lesions are frequently multiple and occur most often in children. Any part of the larynx can be affected, and involvement of the trachea and bronchial tree can occur in severe cases, especially if there is a history of a tracheostomy. Currently, the laser is used to excise papillomas in children; however, regrowth can be so rapid that many children require repeat procedures every few weeks. Most cases eventually go into remission, but some persist into adulthood, and although these lesions are benign, deaths have occurred secondary to pneumonia or airway compromise. The high correlation between children with juvenile papillomatosis and mothers with genital warts suggests a viral etiology. Papillomas do occur in adults, usually men; however, in these cases, the papillomas are less often multiple. Malignancy occurs in a small number of patients with papilloma (see above).

The lesions are exophytic, and CT or MR imaging is not usually done. On plain films, the multiple nodules may be seen impinging on the airway (Fig. 30-72). Chest films are used to evaluate possible pulmonary involvement, which is usually seen as small cavitating nodules.

Benign nonepithelial or mesenchymal tumors include hemangiomas, neural tumors, paragangliomas, lipomas, leiomyomas, rhabdomyomas, chondromas, and a few other rare lesions.[40, 41] Of these, lipomas have a characteristic appearance on both CT and MR imaging because of their high fat content (Fig. 30-73).[85] Chondromas often can be identified by their mineralized matrix and their relationship to the laryngeal cartilage. On imaging, the lesion cannot be reliably diagnosed as benign or malignant unless it has a very aggressive appearance.

Hemangiomas deserve special mention. They are more common in adults than in children, but the pediatric type is more likely to cause airway obstruction and so has received more attention.[86] In adults, hemangiomas (or vascular malformations) are usually localized (Fig. 30-74), tend to be glottic or supraglottic, enhance on CT and MR imaging, and have a fairly high T2-weighted signal intensity.

Hemangiomas of the young can occur anywhere in the larynx but have a predilection for the subglottic area (Figs. 30-75 to 30-77). Hemangiomas arising in the subglottic area are a major clinical problem because, even though they are

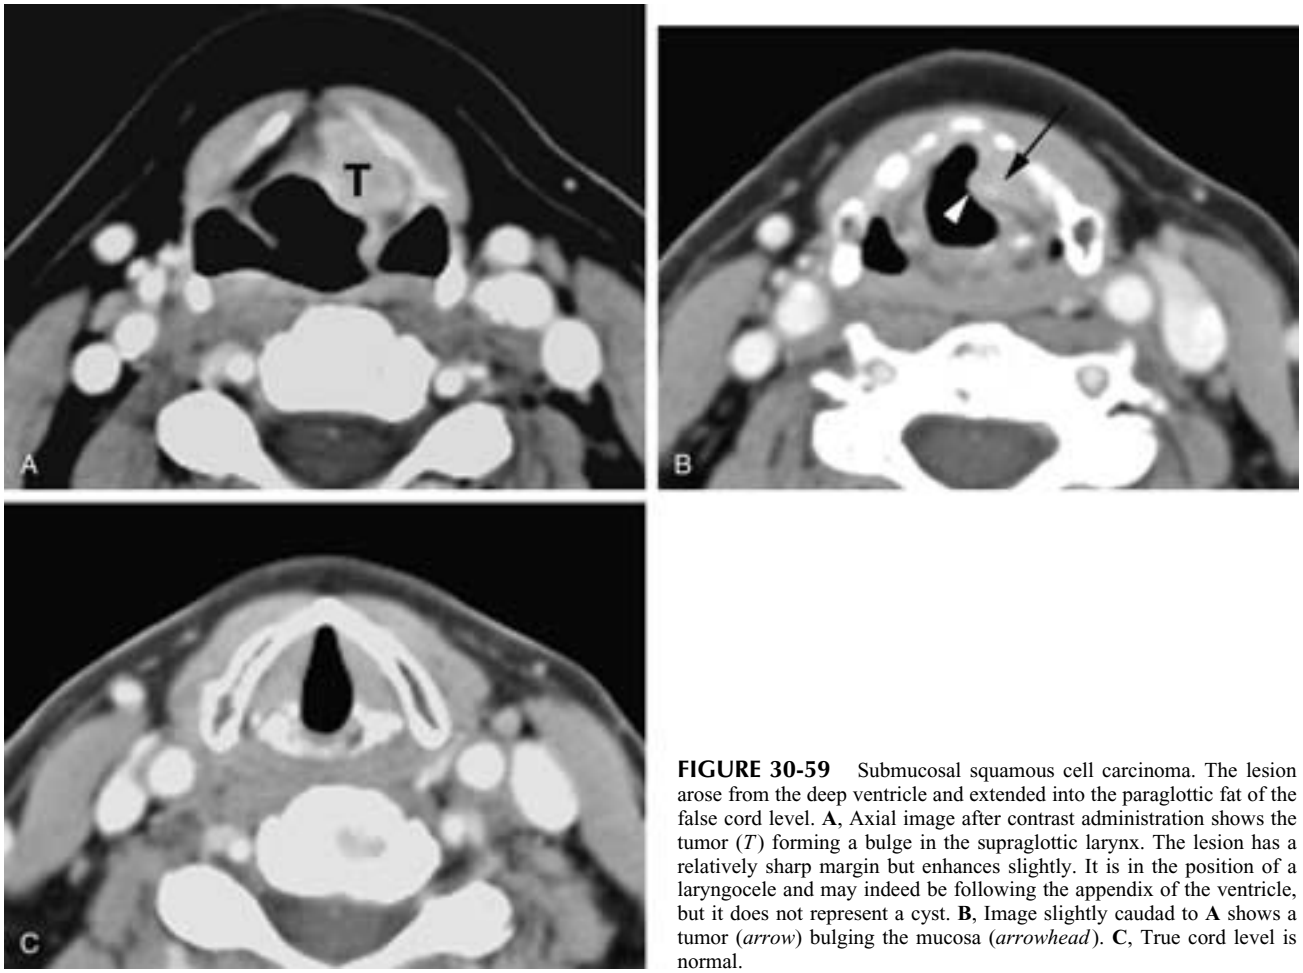

FIGURE 30-59 Submucosal squamous cell carcinoma. The lesion arose from the deep ventricle and extended into the paraglottic fat of the false cord level. **A**, Axial image after contrast administration shows the tumor (*T*) forming a bulge in the supraglottic larynx. The lesion has a relatively sharp margin but enhances slightly. It is in the position of a laryngocele and may indeed be following the appendix of the ventricle, but it does not represent a cyst. **B**, Image slightly caudad to **A** shows a tumor (*arrow*) bulging the mucosa (*arrowhead*). **C**, True cord level is normal.

VIEW IMAGE

expected to regress, airway compromise can force intervention. In a typical pediatric hemangioma, the infant has partial airway obstruction within the first 6 to 12 months of life. Because any inflammation further compromises an already narrowed subglottic area, these patients may present with recurrent croup. Because of venous engorgement, crying also exacerbates the problem. The diagnosis may be suggested by radiography but is usually made by endoscopy when a compressible red or blue mass is seen. Topical epinephrine may cause the lesion to diminish in size; tracheostomy may be necessary while waiting for this to occur. Steroid therapy and surgery have been tried; however, currently, laser excision or reduction is used because of the lower associated operative bleeding. Eventual tracheal stenosis is not uncommon, especially after surgery. The laryngeal lesion is often associated with cutaneous or soft-tissue hemangiomas.

The most common radiographic appearance of a pediatric hemangioma is a localized bulge or concentric narrowing of the subglottic airway. This can be appreciated on CT or MR imaging in the axial, coronal, or sagittal planes. On MR imaging the lesion has a high T2-weighted signal intensity (Fig. 30-77), and on both CT or MR imaging the lesion enhances with contrast. The airway configuration can be easily appreciated on plain films done in several projections. Occasionally, phleboliths may be seen in a larger hemangioma, either with CT or with plain film (usually in somewhat older patients). Hemangiomas of the extralaryngeal neck rarely extend into the larynx.

Paragangliomas (glomus tumors) have been reported in

the larynx, usually in a supraglottic location (Fig. 30-78).[39] These lesions enhance on CT and, as might be expected from their vascular nature, tend to bleed if biopsied. Like hemangiomas, they have intermediate signal intensity on T1-weighted images and high signal intensity on T2-weighted images.

Schwannomas can occur as isolated submucosal tumors, usually in the supraglottic larynx. In neurofibromatosis, an isolated neurofibroma can occur; however, a plexiform, more infiltrative lesion also can diffusely involve the paraglottic structures (Fig. 30-79).[87, 88]

Granular cell tumor is a benign lesion of unknown origin that involves the mucosal membranes of the head and neck.[41] Most theories implicate either a Schwann cell or a more primitive mesenchymal cell origin. The larynx can be involved, and the most common site is the true cord. The epithelium over the granular cell tumor may be hyperplastic and thus may mimic squamous cell carcinoma at direct inspection. Biopsy establishes the diagnosis. The age of occurrence is usually 35 to 45 years, which is younger than the usual age of squamous cell carcinoma.

CYSTS AND LARYNGOCELES

Cysts of the larynx include submucosal cysts and laryngoceles or saccular cysts. Thyroglossal duct cysts may protrude into the supraglottic larynx.

Mucosal cysts can arise anyplace in the larynx that contains submucosal glands.[41, 89] Thus, only the free margin

VIEW IMAGE

of the true cord is spared, and virtually any other location within the larynx is a possible site of cyst development. These cysts are superficial and submucosal, and they protrude into the airway. Symptoms depend on the size and location of the cyst and include dysphagia and respiratory distress. Deep extension is not seen. Vallecular cysts, which often occur in children, are seen anterior to the epiglottis (Fig. 30-80).

The saccule, or appendix, of the laryngeal ventricle is a tubular structure that normally extends cranially into the paraglottic region of the supraglottic larynx (Fig. 30-81). The saccular lumen communicates with the anterior ventricle. If the saccule enlarges, the resultant submucosal mass is called a laryngocele or saccular cyst.[90, 91] If the saccule remains air-filled, many authors refer to the abnormality as a laryngocele. However, if the saccular lumen fills with secretions, the terms *saccular cyst* and *laryngeal mucocele* are often preferred, although some authors simply use the terms *air-filled* and *fluid-filled laryngocele* to describe the lesions. Although a saccular cyst can result from inflammatory mucosal swelling, an obstructing lesion in the ventricle always must be sought.

A laryngocele is referred to as being internal, mixed or combined, or external in type. An internal laryngocele remains totally within the larynx, producing a submucosal supraglottic mass. A combined or mixed laryngocele protrudes through the thyrohyoid membrane, producing both an intralaryngeal and an extralaryngeal mass. The term *external laryngocele* refers to a combined laryngocele that produces little if any supraglottic mass. However, most lesions with an external component also have an internal component, even though it may be small.

A laryngocele can be diagnosed on CT, MR imaging, or even plain films (Figs. 30-82 to 30-87). The internal consistency of the fluid-filled cysts may vary somewhat, depending on their protein content; however, this is apparent only on MR or CT. On CT or MR imaging, the supraglottic ''mass'' can be followed down through the paraglottic area of the false cord to the level of the ventricle. The margin is usually smooth, and the supraglottic fat is not completely obliterated. Thus, the laryngocele is at least partially surrounded by the supraglottic fat. It should be noted that a normal air-filled ventricular appendix can often be seen on axial imaging. This should not be called a laryngocele unless it causes a submucosal deformity of the ipsilateral supraglottic margin.

As mentioned, a laryngocele, although always benign, can be associated with a malignancy in the region of the ventricle (Figs. 30-86, 30-88 and 30-89). The tumor obstructs the outflow of the saccule, causing either trapping of air or, more commonly, retention of mucous secretions. Thus, the ventricular area should be closely examined in patients with a laryngocele or a saccular cyst. In this regard, imaging cannot completely exclude a carcinoma and endoscopy should always be performed. Rarely, a laryngocele can develop after laryngeal surgery, presumably due to local scarring or from positioning of a prosthesis (Fig. 30-90).

The term *laryngopyocele* refers to an infected laryngocele (Figs. 30-91 and 30-92). Due to its size and the associated inflammation, a laryngopyocele can cause airway compromise. Cellulitis can also spread to the lateral neck.

The treatment of a symptomatic laryngocele is surgical. A tracheostomy is often performed because of concern that even minor postoperative swelling or bleeding can compromise the airway.

Although thyroglossal duct cysts (TGDC) are discussed in Chapter 35, they are also briefly mentioned here (Fig. 30-93). At the level of the larynx, a TGDC has a characteristic location just off the midline, insinuated between or deep to the strap muscles positioned against the anterior thyroid ala. These cysts are usually easily distinguished from a laryngocele, because the TGDC has a more anterior location and remains outside the larynx. Occasion-

ally, at imaging, a TGDC appears to protrude into the larynx through the superior thyroid notch. There have also been a few reports of long-standing large TGDCs that have caused deossification of the thyroid cartilage and bulged into the larynx, presenting clinically as a submucosal mass. The treatment was excision without resection of any of the larynx.

INFECTION AND INFLAMMATION

Infections that may come to the attention of the radiologist are usually those of childhood, including epiglottitis or croup. Tuberculosis or other granulomatous diseases are rare, as is perichondritis or infection of the laryngeal cartilages, usually associated with prior RT.[92] Previously, perichondritis and abscesses were caused by typhoid fever, measles, scarlet fever, erysipelas, anthrax, and mycoses.[93] Occasionally, infections of the soft tissues of the neck can involve the larynx secondarily, as can other inflammatory processes such as arthritis and collagen vascular disease.

Croup

Croup is an inflammation of the subglottic larynx with greater or lesser involvement of the trachea and bronchi.

VIEW IMAGE

Occurring in young children (6 months to 3 years of age), croup is usually caused by type 1 parainfluenza virus, but many other organisms occasionally have been implicated. Croup produces a barking cough and stridor. The edema involves the mucosa of the subglottic larynx, and because this tissue is looser in children than in adults, the swollen mucosa can impinge upon the airway. This is usually appreciated best on a frontal film as the ''wine bottle'' or ''steeple-shaped'' airway, with loss of the subglottic arch (Fig. 30-94). If the film is taken during inspiration, there may be ballooning of the pharynx, including the pyriform sinuses. This paradoxical dilatation of the hypopharynx

should alert the clinician to the diagnosis in these patients. On expiration the trachea and subglottis may be distended. Usually, however, the diagnosis is made clinically, and the factors that determine more extensive treatment, such as intubation or even tracheostomy, are clinical rather than radiographic. Plain films are used to confirm the diagnosis and to exclude a foreign body.

Epiglottitis or Supraglottitis

Epiglottitis or supraglottitis occurs in a slightly older age group than croup and is caused by *Haemophilus influenzae*. The child is usually 2 to 4 years old. A sore throat and the inability to swallow are the key clinical features, along with airway compromise. The epiglottis is swollen and has a typical ''cherry red'' appearance.

The lateral radiograph is characteristic and reflects the extent of the abnormality. The epiglottis is thickened, losing its normal sharp, thin or gracile, curvilinear shape (Fig. 30-95). The epiglottis blends into the enlarged AE folds. In severe cases the arytenoid prominence may be swollen. The radiograph is taken to document the disease and to exclude foreign bodies. Because epiglottitis can advance quickly to severe airway compromise, manipulation is minimized, including attempts at direct visualization of the enlarged epiglottis. The patient must never be out of an environment where an emergency tracheostomy can be performed; therefore, radiographs are usually done in the emergency room or even in the operating room. In most institutions, the child is not submitted to the risk of transportion to the radiology department. Therapy includes intubation or even tracheostomy, as well as administration of antibiotics. Decannulization is usually possible within 24 to 36 hours.

Adult epiglottitis or supraglottitis does occur, but it usually is not as life-threatening as it is in the pediatric patient. The findings may mimic radiation change, with enlargement of the AE folds and reticulated streaky density of the supraglottic fat. Rarely, emphysematous epiglottitis has been reported (Fig. 30-96).[94]

Tuberculosis and Other Granulomatous Lesions

Today tuberculosis of the larynx is rare. In the past, it was associated with pulmonary tuberculosis. Clinically, edema is present early, and with more severe involvement, ulceration and necrosis occur, producing a multinodular, irregularly enlarged epiglottis that can be seen on plain films (Fig. 30-97). There are reports of partial auto-epiglottectomies, in which the patient, in a fit of coughing, coughed up the necrotic epiglottic tip. The cricoarytenoid joint can also be involved, causing fixation; perichondritis can also occur.

Rhinoscleroma (Fig. 30-98), Wegener's granulomatosis, T-cell lymphoma (malignant midline granuloma, polymorphic reticulosis), pemphigus, leprosy, syphilis, and numerous mycotic infections all have been noted to rarely involve the larynx.[95] Involvement can be localized to the larynx or can occur in association with pharyngeal involvement (Fig. 30-99). The recent increase in immunocompromised patients has made these rare infections more of a diagnostic consideration.

Immunohistochemical studies have resulted in a reclassification of some midline destructive diseases. Although Wegener's granulomatosis remains an entity with histologic demonstration of noncaseating multinucleated giant cell granulomas and necrotizing vasculitis, midline granulomatosis has now been reclassified as a non-Hodgkin's T-cell lymphoma.[96]

Sarcoid can cause diffuse laryngeal thickening, small nodular lesions, or localized infiltrative lesions, almost all of which are submucosal. No radiographic finding is specific, and the patient usually has other systemic manifestations of this disease.

Neck Infection

Soft-tissue infection arising in the neck can rarely extend into the larynx (Fig. 30-100). Usually there is a diffuse supraglottic edema, although glottic and subglottic disease can occur. On CT, the diffuse soft-tissue thickening typically has an attenuation less than that of muscle, indicating its edematous nature. Although the clinical settings are quite different, the imaging findings of these cases of laryngitis are often similar to those seen in a recently irradiated larynx.

Rheumatoid and Collagen Vascular Disease

The cricoarytenoid and cricothyroid joints are true synovial joints and can be affected by any type of arthritis, including rheumatoid arthritis, that can affect the other synovial joints in the body.[97] Swelling of the cricoarytenoid joint may cause hoarseness, and late sequelae include joint fixation. On CT, this can be identified by irregular sclerosis

Copyright © 2003, Mosby, Inc. All rights reserved.

or erosions in the region of the cricoarytenoid joint, while the soft tissues close to the arytenoid may be swollen.

Relapsing polychondritis is a rare idiopathic, nonsuppurative inflammatory condition affecting various cartilages.[98–101] The cartilages in the ear, nose, larynx, trachea, and joints can be involved. Ocular findings and sensorineural hearing loss have also been described. Airway involvement is present in about half of the afflicted patients, often with significant airway compromise. When the laryngeal cartilages are involved, generalized laryngeal edema can occur.[102] Inflammation can present as high T2-weighted signal intensity along the margins of the cartilage. Sclerosis and enlargement of the cartilage can be present, presumably reflecting a reaction to the inflammation. There can also be demineralization of parts of the cartilage, and diffuse calcification of the involved areas may be present. One report showed considerable calcification in the region of the arytenoid cartilages. Radionuclide bone scans can be positive over the involved region of the larynx and over other affected areas of the body.[24] The tracheal rings may also be affected, with apparent thickening and sclerosis of the cartilage and contiguous soft-tissue changes. Once the carti-

Gastroesophageal Reflux

The presence of gastric acid in the larynx can cause a variety of problems related to the resulting inflammation.[103–105] So-called extraesophageal (esophagopharyngeal) reflux allows gastric secretions to extend above the cricopharyngeus muscle and cause inflammation in the posterior larynx, especially in the interarytenoid region, AE folds, and posterior cord area. As the arytenoid cartilages and true vocal cords become edematous, hoarseness can occur. Often these patients present with recurrent episodes of low-grade hoarseness, the onset of which is first noticed in the mornings. If laryngoscopy is performed shortly after the onset of symptoms, a characteristic redness can be seen localized to the arytenoids and posterior true cords. Gastric acid reflux has also been implicated in the formation of vocal cord nodules or granulomas, pharyngeal edema, and even inflammatory changes in the trachea. Some have suggested that the findings may mimic supraglottitis or other inflam-

VIEW IMAGE

matory disease in the larynx. The treatment is directed to the reflux, which, once controlled, allows the laryngeal lesions to resolve.

TRAUMA

A variety of direct blows and penetrating trauma to the neck can injure the larynx.[106] Vehicular accidents account for most of the significant trauma to the larynx and upper trachea, with the larynx being crushed between the dashboard or steering wheel and the cervical spine. In children, the larynx is higher in position relative to the mandible and is thus relatively protected. However, in the adult, the lower position of the larynx relative to the mandible makes it more vulnerable to trauma.

In many circumstances, the radiologic examination cannot be performed acutely because of airway compromise. However, as early definitive surgical intervention is associated with better results, the diagnostic evaluation should not be substantially delayed.

If the cartilage is well calcified, fractures can be seen on plain radiographs; however, CT usually gives better visualization.[107] Of particular interest should be the presence of any cartilage fragments that either impinge on the airway or appear to perforate the mucosa. These fractures and perforations predispose the region to infection of the

cartilage and further airway compromise, so endoscopy is performed to assess for any mucosal tears. If the mucosa is torn, air can often be seen in the adjacent soft tissues and is visible on plain films and CT. A hematoma may develop and appear either as a mass or as an obliteration of the normal fat density in the upper larynx (Fig. 30-101).

Fractures of the larynx can involve the thyroid cartilage, cricoid cartilage, or both cartilages.[108] Thyroid cartilage fractures are either primarily vertical or horizontal (Figs. 30-102 and 30-103). Vertical fractures result from the splaying of the thyroid cartilage as it is pushed against the spine. A horizontal fracture usually crosses both thyroid alae, and there is often coexistent supraglottic soft-tissue injury (Fig. 30-104). The superior fragments of the thyroid cartilage can be displaced posteriorly, and the thyroepiglottic ligament or petiole of the epiglottis may be torn, resulting in a dislocated or avulsed epiglottis (Fig. 30-105).[109] The hyoid bone also may be fractured. Vertical fractures of the thyroid cartilage are best appreciated on CT. However, horizontal fractures are in the plane of the axial CT scan and therefore may be difficult to demonstrate on these images. As multidetector CT allows multiplanar visualization of these fractures, this technique may help in the diagnosis of horizontal fractures.

Occasionally on axial CT, a patient has an asymmetrical curvature to the thyroid cartilage, with one side bowing inward, often creating a submucosal fullness on that side. Although there is no immediate history of trauma, careful questioning may reveal a history of previous insult to the larynx. Although most authors believe that such an appearance represents the late sequelae of old trauma, a developmental variation is also a possibility.

Cricoid fractures cause a collapse of the normal cricoid ring (Figs. 30-106 and 30-107). Almost always there is more than one fracture, usually with both sides of the cricoid ring being broken to create anterior and posterior fragments. The anterior fragment is pushed posteriorly and impinges on the airway, and the free end of a fragment may perforate the mucosa. The fractures may be difficult to appreciate in younger patients because the arch of the cricoid cartilage is not as well calcified; however, usually the cartilage is dense enough that it can be seen on CT (Figs. 30-107 and 30-108).

The lateral aspect of the laryngocele (*arrowhead*) caused a significant bulge in the neck. Tumor fills the opposite supraglottis (*T*). The smaller laryngocele (*arrow*) is seen on the side of the tumor with an air-fluid level. **C**, Lower scan shows the tumor (*T*), the intralaryngeal segment (paraglottic space) of the laryngocele (*arrow*) and the external component (*arrowhead*).

VIEW IMAGE

Key findings are the shape of the airway and the presence of subglottic swelling. At the level of the cricoid, the normal subglottic airway is slightly oval. A subtle fracture with minimal displacement gives the airway a rounder appearance, and edema causes increased soft tissue between the cartilage and the air column. If these important fractures are to be detected, familiarity with the normal appearance of the subglottic area is crucial. Fractures of the cricoid usually require surgical intervention, with repositioning of the fragments and stabilization with either sutures or a plate.

Laryngotracheal separation is a complete tear of the trachea, and because of loss of the airway, it is usually fatal (Fig. 30-109). Plain radiographs may show the malalignment of an incomplete separation. Few of these patients survive to be imaged. Those who do usually already have had a tracheostomy.

Arytenoid dislocation results in an abnormal position of the arytenoid relative to the cricoid cartilage (Fig. 30-110). Often there is an associated fracture of one of the larger laryngeal cartilages, but some dislocations have been reported with fairly minimal trauma to the side of the neck.

Minimal dislocations probably can be missed at imaging, but the radiologist should comment on the position of the arytenoid cartilage relative to the articular tubercle on the upper margin of the cricoid.

A dislocation of the cricothyroid joint is seen as a malalignment of the thyroid and cricoid cartilages (Fig. 30-111). A true dislocation of this joint is considered to be very rare. Usually the inferior horn of the thyroid cartilage is fractured, allowing the apparent separation of the cartilages. The thyroid cartilage may be rotated to one side, while the cricoid retains a normal orientation. These ''dislocations'' usually result from more severe trauma, and usually other cartilage fractures are present. Before diagnosing a dislocation of the cricothyroid joint, it is important to follow the inferior horn of the thyroid cartilage to its articulation with the cricoid. Even slight obliquity of the scan can cause an apparent widening of the space between these two cartilages, and this effect should not be mistaken for a fracture.

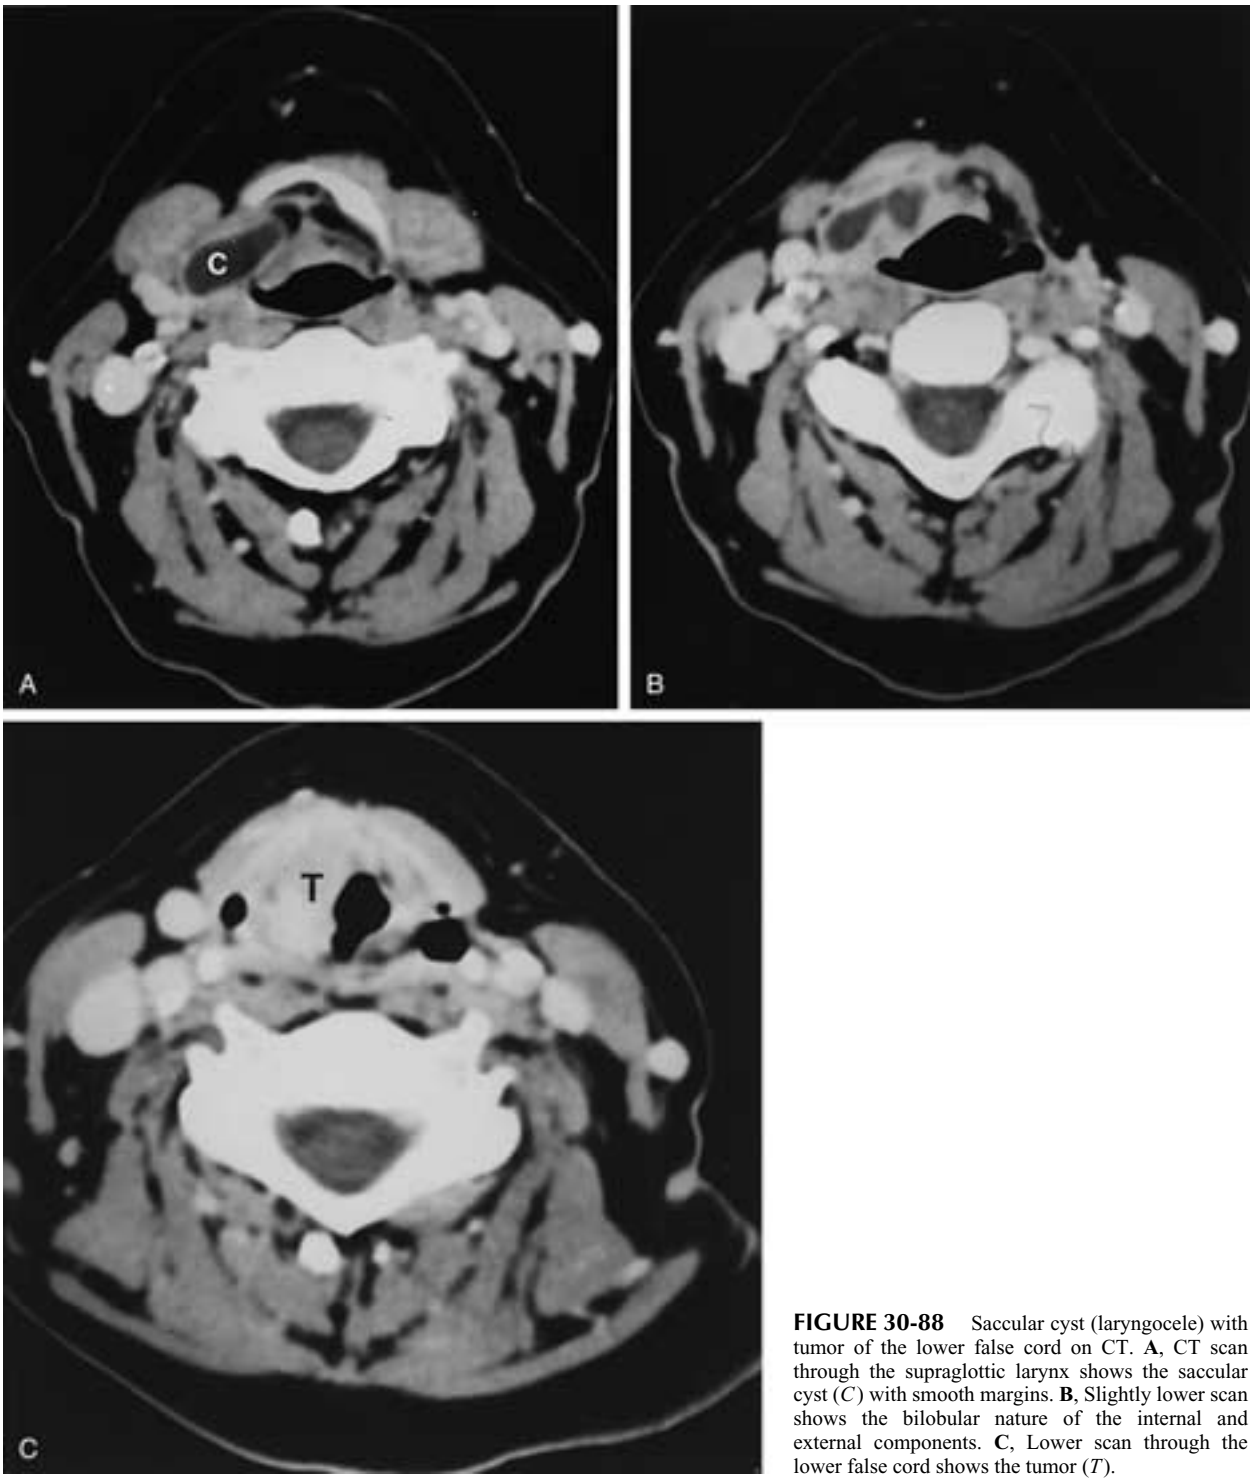

FIGURE 30-88 Saccular cyst (laryngocele) with tumor of the lower false cord on CT. **A**, CT scan through the supraglottic larynx shows the saccular cyst (*C*) with smooth margins. **B**, Slightly lower scan shows the bilobular nature of the internal and external components. **C**, Lower scan through the lower false cord shows the tumor (*T*).

FIGURE 30-89 **A**, Saccular cyst (laryngocele). Well-defined cyst (*C*) fills the supraglottic larynx. Note the definite separation (*arrowhead*) from the mucosa. **B**, Scan inferior to **A** shows a tumor at the level of the ventricle and the true cord. *T*, Tumor.

Foreign bodies may be the result of penetrating trauma but more commonly are the result of either ingestion or aspiration. The pyriform sinus is a common location for a foreign body to lodge in, and from this point the foreign body can either enter the laryngeal airway and continue into the trachea or bronchi or penetrate anteriorly into the paraglottic space of the larynx.

Burn injury of the larynx can result from the inhalation or ingestion of hot material or gases.[110] The supraglottic larynx is most likely to be involved, and generalized edema can occur. Several cases of ingestion of hot foreign substances have been related to ''melting'' crack cocaine. Small bits of steel wool heated to melt the cocaine can cause a more localized burn in the pyriform sinus or AE fold (Fig. 30-112). The imaging findings can mimic tumor, creating diagnostic problems if the pertinent history is not available.

CONGENITAL LESIONS

Radiology can be helpful in assessing congenital laryngeal anomalies. Plain radiographs can assess the size of the airway or the length of a stenosis. CT in the axial plane provides a good cross-sectional view of the airway, allows an estimate of the length of a stenosis, and characterizes the tissues deep to the mucosal surface. Spiral CT can acquire an entire set of images quickly and allows multiplanar reformations to better characterize the length of the abnormality.

esophageal septum, isolating the trachea from the developing foregut. At one point, the laryngeal lumen is temporarily occluded but reopens or recanalizes. The cartilages form from the mesenchyme on either side of the primitive respiratory passage, and the components from either side fuse to form the cricoid and thyroid cartilages. Congenital abnormalities are related to problems of the developmental process or simply are the result of delays in normal maturation (see also Chapter 29).[111–113]

Laryngomalacia

Laryngomalacia represents delayed development of the laryngeal support system.[114] The structures are present but are not firm enough to keep the larynx continually open. The supraglottic larynx is primarily affected, and the epiglottis alone may be floppy or the entire supraglottic larynx may collapse on inspiration. The infant outgrows the abnormality as the cartilages mature; however, a tracheostomy may be needed to maintain an airway until this laryngeal maturation is completed.

Subglottic Stenosis

Subglottic stenosis is a narrowing of the subglottic larynx from the true cord down to the lower cricoid.[114–116] The patient normally outgrows this soft-tissue stenosis, but a tracheostomy may be needed before this maturation is completed. Plain radiographs can demonstrate the narrowing.

Less commonly, a rare cricoid abnormality can occur in which the cricoid shape is a narrow ellipse rather than round (Fig. 30-113). This elongated shape narrows the airway.[115] As the cricoid is not calcified at this age, imaging is unlikely to be helpful. However, because of the hard consistency of the subglottic wall, the diagnosis is suggested by endoscopy.

Webs and Atresia

Small webs can be seen at any level of the larynx, but they are usually at the level of the true cords. Subglottic webs may be associated with cricoid abnormalities. Webs are seldom evaluated radiographically, but radiographs may be done to exclude other abnormalities.

Atresia of the larynx is a failure of complete recanalization, and no airway exists through the larynx (Fig. 30-114). The trachea, however, is present, and a tracheostomy at birth is life-saving.

There have been reports of laryngeal or tracheal atresia diagnosed prenatally using ultrasound.[117, 118] Fluids are secreted into the lungs and cannot pass out of the bronchial tree unless there is a coexisting tracheoesophageal communication. Without such a communication, the bronchial tree

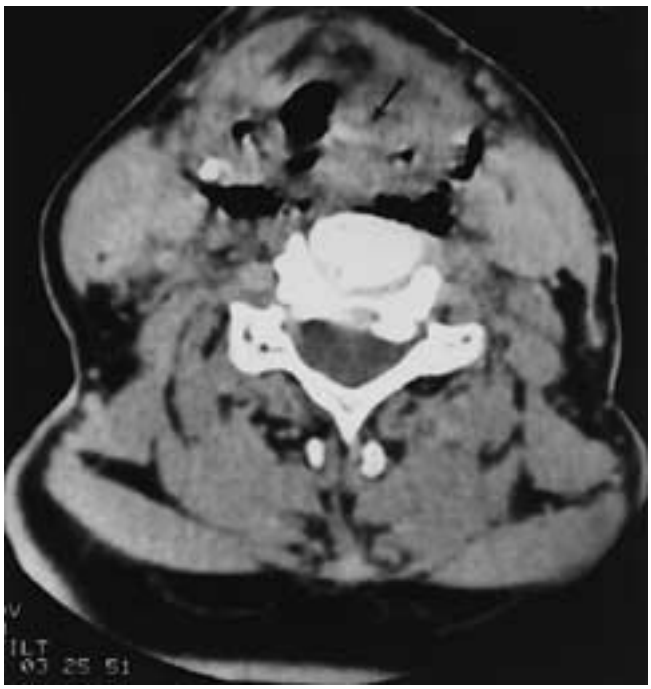
enlarges and the lungs become distended with fluid. The enlarged lungs are echogenic because of the small fluid-filled spaces present. A tracheostomy done at birth is crucial if there is to be any hope of survival; however, in most instances the anomaly is fatal.



VIEW IMAGE

FIGURE 30-101 Vehicular injury. Axial CT of a hematoma of the larynx and laceration of the pharynx. There is a hematoma (*arrow*) of the AE fold. The gas in the soft tissues is from laceration of the pharyngeal wall.

Clefts

Laryngotracheal clefts are exceedingly rare and are presumed to be the result of failure of complete fusion of the tracheoesophageal septum as it grows to separate the trachea from the esophagus.[36, 114, 119] The cricoid cartilage, which results from a fusion of cells from the mesenchyme on either side of the airway, may also be affected. Although an isolated cleft of the larynx does occasionally occur, frequently a laryngeal cleft is associated with a tracheal cleft. The child aspirates and may have multiple pneumonias.[120]

Subglottic Hemangiomas

Subglottic hemangiomas were mentioned in the preceding section titled Benign Tumors, but they are included here because they are as much vascular malformations as they are tumors. The lesion usually can be seen as a subglottic narrowing on a lateral neck radiograph. Therapy is conservative, but tracheostomy may be necessary.

Other Anomalies

Other rare anomalies such as a bifid epiglottis or duplication anomalies have been reported.

STENOSIS

Stenosis of the larynx or upper trachea can be either a congenital anomaly, a sequela of trauma, or the result of therapy. The most common stenosis results from prolonged

cuffed tube intubation (Figs. 30-115 and 30-116). The position of the stenosis secondary to such prolonged intubation or a tracheostomy is characteristic, starting first along unforgiving anterior and lateral walls. Eventually, circumferential stenosis occurs, with involvement of the posterior membranous wall. Stenosis secondary to trauma is more variable, while ingestion of corrosive materials usually causes strictures of the posterior supraglottic larynx. Plain films or conventional tomograms are still good methods for assessing the length of the stenosis or the extent of a ''granuloma'' (Fig. 30-117). Two projections are used, usually frontal and lateral. Alternatively, spiral CT can be used.

FIGURE 30-105 Avulsion of the epiglottis, sagittal MR image. In this midline scan the area of low signal, representing the epiglottis (*arrowheads*), is not straight, but rather bends abruptly in this patient with a fracture avulsion of the epiglottic cartilage. The point of angulation (*arrow*) is thought to represent a site of fracture. *T*, Tracheostomy. (From Duda JJ Jr, Lewin JS, Eliachar I. MR evaluation of epiglottic avulsion. AJNR 1996;17(3):563–566.)

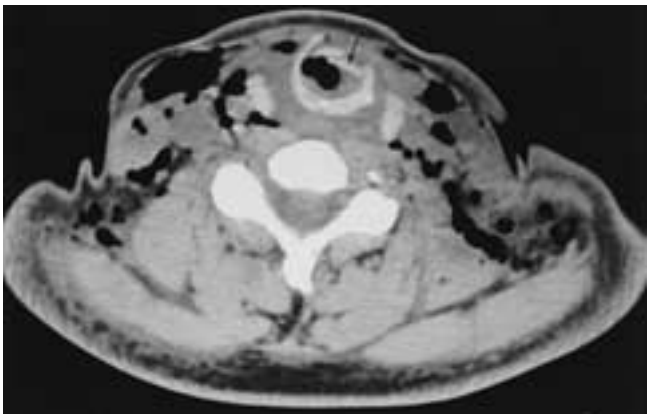

FIGURE 30-106 Axial CT shows fracture of the cricoid, with posterior positioning of the fragments (*arrow*) into the airway.

CT in the axial plane visualizes a cross section of the airway, and this allows characterization of the stenosis. Soft-tissue scars and granulomas can significantly compromise the airway, without any change in the cartilage, or the cartilage can collapse and be displaced into the airway, creating a ''hard'' stenosis (Fig. 30-118). This has obvious implications in planning therapy because if the cartilage is not involved, simple lysing of the soft tissues may be adequate therapy. However, if the cartilage itself is impinging on the airway, a more extensive reconstruction will be necessary. A limited segment of the trachea may be resected and the lower trachea may be surgically released and pulled up, to be anastomosed with the remaining normal trachea.

Although these problems primarily relate to the trachea rather than the larynx, a traumatically displaced fragment of the anterior cricoid can cause significant narrowing of the subglottic area, and scarring can further narrow the airway. Anterior and posterior commissure webs or scars are usually visible endoscopically. However if there is stenosis or scarring at the level of the cords, the lack of full abduction may limit distal visualization, and imaging may be performed to assess possible extension into the subglottis. Such scarring will be seen on imaging as soft-tissue fullness along the inner cortex of the cricoid, where normally no significant soft tissue is present separating airway and the cartilage.

Conventional CT has been limited to the axial plane. However, spiral CT, particularly with multidetector technology, provides excellent-quality reformatted images. Thus, the vertical exent of a stenosis can be defined at the same time that the character of the wall is examined. MR imaging can also provide good multiplanar images, but it does not show the calcified cartilages as well as CT. However, MR imaging has proven useful in the examination of lower tracheal narrowing and in the evaluation of various vascular rings.

When describing a tracheal stenosis, the radiologist should note how far the upper margin of the stenosis is from the bottom of the cricoid cartilage. Note should be made of the distance of the bottom of the stenosis from the carina. These landmarks are readily used anatomic reference points for the endoscopist. Secondly, the length of the stenosis

should be noted. Last, the maximal amount of reduction of the cross-sectional tracheal airway relative to the normal trachea either above or below the stenosis should be mentioned. As a general guide, if a patient has normal pulmonary function, a 50% cross-sectional airway narrowing is associated with dyspnea on exertion. With compromised pulmonary function, lesser degrees of stenosis will cause dyspnea on exertion. Greater degrees of stenosis are associated with dyspnea at rest.

VOCAL CORD PARALYSIS

Vocal cord paralysis can be categorized as a superior laryngeal nerve deficit, a recurrent laryngeal nerve deficit, or a total vagal nerve deficit.

Superior Nerve

The only muscle innervated by the superior laryngeal nerve is the only extrinsic muscle of the larynx, the cricothyroid muscle, which extends between the cricoid and thyroid cartilages. Contraction of the cricothyroid muscle normally pulls the anterior cricoid ring up toward the lower margin of the thyroid cartilage. This rotates the upper cricoid lamina and the attached arytenoids posteriorly, putting tension on the true vocal cords. If the cricothyroid muscle is paralyzed, unopposed contraction of the innervated contralateral muscle rotates the posterior cricoid to the paralyzed side. At laryngoscopy, the posterior larynx (arytenoid) is deviated toward the side of the nerve abnormality.

With this history, the radiologist should examine the neck for a lesion along the course of the vagus nerve (X), which passes through the pars nervosa of the jugular foramen and follows the carotid sheath to the level of the larynx. Usually in these cases, imaging fails to identify a lesion.

Recurrent Nerve

More commonly, one encounters a paralysis of the recurrent laryngeal nerve.[121] All of the intrinsic laryngeal muscles are innervated by this nerve. The classic findings of recurrent laryngeal palsy can be identified on plain films, tomography, CT, and MR imaging (Figs. 30-119 to 30-122).

Most of the findings are secondary to atrophy of the TAM. As the muscle atrophies, the cord becomes thinner and more pointed in the coronal plane, with loss of the subglottic arch. As the muscle diminishes in size, the ventricle enlarges and can be prominently seen on axial images, at times extending almost to the inner surface of the thyroid cartilage. The ipsilateral arytenoid is anteromedially placed, and the ipsilateral pyriform sinus enlarges as the AE fold falls medially and appears slightly thickened. The ispilateral vallecula may also be enlarged. On fluoroscopy, different maneuvers show the lack of motion of the paralyzed cord and normal motion of the contralateral side.

The posterior cricoarytenoid muscle is closely applied to the posterior surface of the cricoid, an area well seen on axial images. In cases of recurrent nerve paralysis, the muscle atrophies and fat infiltration may be appreciated.[122]

When studying an abnormality of the recurrent laryngeal nerve, the radiologist must examine the pathway of the vagus and recurrent laryngeal nerves. The vagus nerve exits the skull base in the jugular foramen and then runs in the posterior portion of the carotid sheath. Lower in the neck, the nerves move more anteriorly. On the left side, the recurrent nerve leaves the sheath and passes anterior to and then under the aortic arch before ascending in the tracheoesophageal groove to enter the larynx near the cricothyroid junction. On the right side, the recurrent nerve curves under and around the right subclavian artery to ascend in the tracheoesophageal groove to the larynx.

MR image. **A**, Supraglottic level shows enlargement of the pyriform sinus (*arrow*) and anterior tilting of the AE fold (*arrowhead*). **B**, Level of the true cord. There is enlargement of the ventricle (*arrow*) as the TAM on the involved side atrophies. The vocal ligament (*arrowhead*) remains in place. **C**, The true cord on the left side shows a normal signal intensity. Thyroarytenoid muscle (*TAM*). **D**, Image slightly caudad to **C** shows the abnormal signal and decreased size of the posterior cricoarytenoid (*large arrow*) on the involved side. Compare with the bulk of the posterior cricoarytenoid muscle on the normal side (*arrowheads*). Anterior cricoarytenoid muscle on the normal side (*small arrow*).

Adductor Paralysis

Rare cases of adductor paralysis have been described. This paralysis affects the muscles that bring the cords together but spares the posterior cricoarytenoid muscle. This muscle stretches from the posterior surface of the cricoid to the lateral aspect of the muscular process of the arytenoid. It is the only muscle that rotates the cord outward, and because the posterior cricoarytenoid muscle is unopposed, the cord remains in a lateral position (Fig. 30-123). The lesion affects certain fibers of the recurrent laryngeal nerve while sparing others. The cause of this abnormality is poorly understood, although an intracranial etiology has been postulated.[123]

MISCELLANEOUS CONDITIONS

Amyloid can affect the larynx either as an isolated lesion (primary) or as part of a more generalized disease (secondary). The deposits produce nodules or thickened zones deep to the mucosal surface.[124] The findings on CT may be mistaken for a submucosal tumor (Fig. 30-124). Amyloid deposits may calcify (Fig. 30-125).

Diverticula of the pharynx are herniations of mucosa through dehiscences in the muscular constrictors. Pseudodiverticula are outpouchings of the pharynx due to focal weakness of the pharyngeal wall. These pharyngoceles have been noted in patients who play wind instruments, and most are located at the level of the thyrohyoid membrane (Figs.

30-126 and 30-127). The diverticula are usually incidental findings on barium swallow examinations and have been referred to as ''dog ears'' on a frontal barium swallow film.

A Zenker's diverticulum is an outpouching of pharyngeal mucosa through the inferior constrictor muscles. Most diverticula herniate through Killian's dehiscence, the weak area in the pharyngeal wall located in the gap between the uppermost cricopharyngeus and the inferior most oblique fibers of the inferior pharyngeal constrictors. Although the actual dehiscence or entrance to the diverticulum is in the midline, the diverticulum usually protrudes to the left side. The neck or the anterior wall of the diverticulum is well appreciated on a barium swallow, using oblique, frontal, and lateral projections (Fig. 30-128). Although a Zenker's diverticulum can occasionally be seen on CT (Fig. 30-129), it is easier to diagnose on a barium swallow.

A second weak point in the wall occurs laterally between the cricopharyngeus and esophageal musculature, at the so-called Killian-Jamieson area. Herniations through this area have been reported but are rare.

When there is a Zenker's diverticulum, the cricopharyngeus is usually prominent; however, the cricopharyngeus may also be prominent without a diverticulum (Fig. 30-130). Failure of the muscle to relax completely during swallowing can cause dysphagia, and occasionally a small collection of barium can be seen just above this muscle after the barium column has passed. This residual contrast is thought by

some to represent a ''primordial Zenker's diverticulum,'' although few of these cases are thought to develop into the classic Zenker's diverticulum. If there is cricopharyngeal achalasia, some authors have suggested that this condition can be related to the development of a Zenker's diverticulum. Failure of relaxation of the cricopharyngeus has also been associated with gastric reflux and other abnormal motility problems in the esophagus, as well as with neurologic conditions affecting the medulla.

VIEW IMAGE

FIGURE 30-126 Barium swallow, pharyngeal diverticula. There is a small outpouching extending through the pharyngeal wall (*arrows*).

Benign Cartilage Changes

Cartilage is a malleable tissue and can be remodeled by pressure or eroded by malignancy. Pressure capable of causing such remodeling can be the result of prominent osteophytes of the spine, benign tumors, or, rarely, an enlarged thyroid gland (Figs. 30-131 and 30-132).[125]

Occasionally, an ala of the thyroid cartilage can bow medially. As described earlier, this may be the result of old trauma, although most often there is no history of trauma. The abnormal cartilage shape may cause a medial bulge in the wall of the larynx that endoscopically mimics a submucosal mass. On CT or MR imaging, the lack of obliteration of the paraglottic fat makes tumor very unlikely (Fig. 30-133).

Osteophytes of the Spine

Large osteophytes arising from the anterior cervical spine can occasionally cause dysphagia.[126] These osteophytes can cause a significant mass effect on the posterior pharyngeal wall or even rarely interfere with the normal movement of the larynx during swallowing. Most often, such osteophytes are seen and the patient has no symptoms related to the area. However, if there is any cause of limitation of laryngeal movement (prior surgery, irradiation, tumor infiltration, neurologic deficit), these osteophytes can cause symptoms, presumably reflecting the combined effects of the limited laryngeal movement and the posterior retropharyngeal mass.

FIGURE 30-128 Zenker's diverticulum. Lateral film shows a large diverticulum with a wide entrance (*arrowheads*) and the barium column of the true esophagus continuing anterior to the diverticulum (*arrow*). The level of the persistent cricopharyngeus is at the level of the anterior arrowhead. This diverticulum was somewhat unusual because of its midline rather than its usual left-sided position.

Carotid Position

Frequently the carotid artery deviates medially between the pharynx and spine (Fig. 30-134). Although not likely to cause symptoms, this unusual position should be mentioned, especially in patients for whom surgery is contemplated.

Postsurgical Changes

The appearance of the neck after surgery varies, depending on the procedure performed. However, there are certain general postoperative and postradiation appearances in the larynx and neck that are fairly characteristic.

After a total laryngectomy, the normal laryngeal landmarks are no longer present. But as the fascial layers are disrupted during the surgery, the gullet or pharyngoesophageal remnant may migrate anteriorly and should not be mistaken for an airway. The esophagus may actually protrude between the lobes of the thyroid gland, mimicking the trachea (Fig. 30-135). The tracheostomy is usually seen just above the sternal notch, thus identifying the actual airway.

A radical neck dissection removes the sternocleidomastoid muscle and jugular vein, as well as the surrounding nodes.[127] The thyroid gland may assume a rounder shape than normal because of the disruption of the bordering fascial layers. This appearance may mimic a tumor recurrence.[128] The gland may also mimic a blood vessel because of the intrinsically high iodine content of the normally functioning thyroid gland and the highly vascular nature of the gland. The various modifications of neck dissections are described in Chapter 43.

The normal laryngeal structures are obviously missing on a barium swallow done after total laryngectomy.[129] At

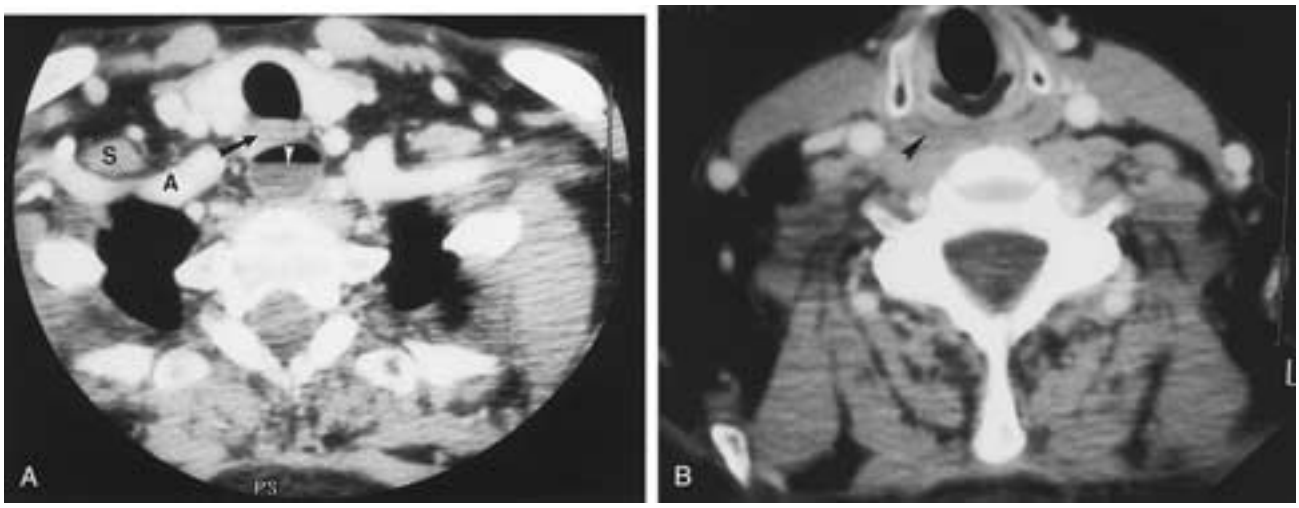

FIGURE 30-129 Zenker's diverticulum. Axial CT. **A**, An air-fluid level (*arrowhead*) is seen within the diverticulum. The actual esophagus (*arrow*) is seen just anteriorly. *A*, Subclavian artery; *S*, anterior scalene. **B**, More superior scan shows the intact pharyngeal wall (*arrowhead*) at the level close to the cricopharyngeus muscle. The abnormality (not shown) actually extends through the various fibers of the muscle.

surgical closure the mucosa is pulled together, often causing a ridge to form just posterior to the tongue base. This ridge can mimic an epiglottis (Fig. 30-136) and has been called the pseudoepiglottis. This is also the area where most postoperative fistulas occur.

Often, a contrast swallow is performed 7 to 10 days after laryngectomy, before the patient is allowed to eat. Barium can be used, but if a fistula into the soft tissues is present, the residual barium can interfere with follow-up studies. If there is no clinical concern that a fistula passes directly into the trachea, meglumine diatrizoate (Gastrografin) can be used as the contrast agent, with careful fluoroscopic control to exclude any communication with the airway. If significant aspiration occurs, the hypertonic Gastrografin can cause pulmonary edema. Care must be taken even if there is a sinus tract to the skin, because Gastrografin can track along the surgical dressing and then go into the tracheal stoma. Before choosing a contrast material, the radiologist should determine whether the surgeon has purposely created a fistula or placed a valve between the trachea and the esophagus. If a valve has been placed, a small amount of contrast material may pass into the trachea, and Gastrografin should not be used. The role of nonionic contrast in this situation has not been fully assessed.

In a supraglottic laryngectomy, all of the normal laryngeal structures above the true vocal cords are removed.

FIGURE 30-130 Lateral barium swallow, slightly prominent, persistent cricopharyngeus (*arrowhead*). There is a small collection of barium (*arrow*) just above the muscle band. This is sometimes referred to as a *primordial Zenker's diverticulum*.

VIEW IMAGE

FIGURE 30-132 Axial CT. **A**, Large multinodular goiter causing shortening and remodeling of the lateral aspect of the thyroid ala (*arrowhead*). **B**, Bone algorithm showing the intact cortical line of the remodeled cartilage (*arrow*).

The hyoid may or may not be included in the resection. A CT scan through the true cords usually appears relatively normal, and the arytenoids usually remain, although one arytenoid may be removed (Figs. 30-137 and 30-138). Although a large portion of the thyroid cartilage has been removed, at the level of the true cords the cartilage should have a normal appearance.

After a supraglottic laryngectomy, in the early postoperative period, some aspiration is almost always present. Because of this, if a contrast swallow is done, Gastrografin should not be used. A barium swallow shows absence of the epiglottis and supraglottic structures, and usually some aspirated barium coats the vocal cords. A follow-up examination should be done after the patient has been trained in the various maneuvers used to help prevent aspiration.

Vertical hemilaryngectomy removes the true and false cords on one side of the larynx. The vertical hemilaryngectomy may also be extended to take the anterior portion of the opposite cord. The soft tissue on the resected side of the larynx may be flat, or a soft-tissue fullness may be present near the level of the true cord, representing either an

attempted reconstruction of the cord (Figs. 30-139 and 30-140) or a reaction of the mucosa to the trauma (pseudocord) resulting from the functioning contralateral cord hitting against it. In some cases, a strap muscle (sternohyoid) may be passed across the larynx and attached to the arytenoid, thus providing bulk against which the opposite cord can appose. In this instance, the corresponding muscle area outside the larynx is diminished, and there is excess tissue present within the larynx at the level of the cord on the resected side.

The amount of thyroid cartilage resected depends on the extent of the lesion. The resection always extends to the midline and often extends a variable distance along the opposite side. The outer perichondrium of the thyroid cartilage is left intact, and some regeneration of the thyroid ala often occurs. One arytenoid may be removed if the tumor reaches the vocal process. The cricoid usually remains intact, although some surgeons remove the upper portion of this cartilage if the tumor margin warrants such a resection.

The variability of the postoperative appearance is greater with the vertical hemilaryngectomy than it is with the supraglottic partial laryngectomy. Still, on imaging, some comments can be made regarding the possibility of deep recurrence, especially if a baseline scan is available.

The supracricoid partial laryngectomy (SCPL) with cricohyoidepiglottopexy (CHEP) or cricohyoidopexy (CHP) removes parts of the true cords. The cricoid is pulled up to the hyoid bone, and parts of the epiglottis remain in the CHEP (Fig. 30-141).

The near-total laryngectomy of Pearson et al. resembles a vertical laryngectomy but continues downward to include part of the upper cricoid.[67, 68] The contiguous soft tissue

is variable, depending on the pharyngeal flap used to reconstitute the airway.

Reconstruction of a pharyngeal defect can be done by a primary closure of the remaining soft tissues, a jejunal interposition, or various flaps (e.g., the deltopectoral flap). On imaging, the jejunal interposition can have a tortuous appearance through the neck, but usually it is in the midline.[130] A flap reconstruction alters the imaging appearance on the side of the neck; this topic is discussed in Chapter 43.[127]

Radiation Changes

Radiation is used to treat many laryngeal lesions, either as the primary therapy or in conjunction with surgery. If laryngeal irradiation has been performed, the resulting mucosal changes can confuse the postoperative imaging assessment of possible tumor recurrence.[131, 132]

Relatively low doses of radiation can cause mucositis and throat pain. Higher doses result in deeper edema and fibrosis and can be associated with perichondritis and chondronecrosis. Almost all patients receiving 60 to 65 Gy will have definable changes in the soft tissues of the larynx. Clinically, the epiglottis thickens and the arytenoids swell, often before the course of radiation is complete. Although gradual improvement is probable, some degree of change persists because of fibrosis and damage to the microvasculature.[133]

CT shows a diffuse thickening of the epiglottis and prominence of the soft tissues in the aryepiglottic folds, in the false cords, and around the arytenoids (Figs. 30-142 and 30-143). There is streaky increased attenuation in the

VIEW IMAGE

preepiglottic and paraglottic spaces (dirty fat or reticulation). The true vocal cords and subglottic larynx are usually fairly normal in appearance. However, in patients who have an excessive reaction to irradiation or who are heavily irradiated, edema of the true cords and subglottis can occur.

Perichondritis is an inflammation or infection of the cartilage. High doses of radiation can cause necrosis and collapse of the cartilages, and irradiated tissue is less resistant to infection than normal cartilage. A deep biopsy of an irradiated larynx (looking for a recurrent tumor) may result in perichondritis, and this may lead to chondritis and chondronecrosis. The CT findings are usually superimposed on the changes previously mentioned. Perichondritis causes edema around the cartilage, and at times gas bubbles can be seen. The cartilage may collapse and fragment, assuming unusual angles on the axial scans (Fig. 30-144). Both perichondritis and chondronecrosis are much more significant clinical problems than those encountered in an uncomplicated irradiated larynx.

Radiation may also lead to a collapse of cartilage invaded by a tumor. This is not necessarily due to a perichondritis or radiochondronecrosis. Rather, in these cases, tumor has replaced the cartilage and has actually become part of its support structure. As the tumor regresses in response to the irradiation, this support structure is lost, and the eroded cartilage collapses.

Stents, Tubes, and Teflon

Stents or bone grafts may be used to rebuild the anterior arch of the cricoid cartilage (Fig. 30-145). They are placed in

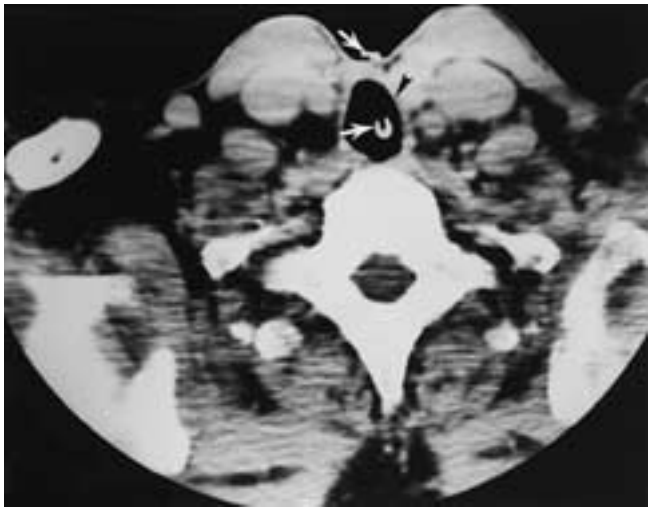
an effort to maintain or improve the cricoid lumen as part of the treatment of laryngeal stenosis or as part of a reconstruction after trauma or surgery. Metal plates are usually used to stabilize the bone grafts and fragments.

Tracheostomy tubes and speaking (voice) tubes can be seen in the lower neck (Fig. 30-146). A tracheostomy tube is usually placed at the level of the midcervical trachea, but if the tracheostomy was done as an emergency procedure, it may extend through the cricothyroid membrane. Secretions can accumulate above the tracheostomy, and there is usually mucosal swelling extending up to include the subglottic larynx. This may mimic tumor, especially in the immediate subglottic region (Fig. 30-146). The secretions usually have a lower CT attenuation than does a recurrent tumor, particularly if contrast is given, and the mucosal edema tends to be very uniform in thickness, with no localized nodularity to suggest tumor.

The various voice valves used to force air from the trachea to the esophagus for use in esophageal speech are seen in the lower neck of patients who have had a total laryngectomy. These valves are most often noted on CT or barium swallow examinations. They are much smaller than a tracheostomy tube and rarely can be aspirated into the lung (Fig. 30-147).

Teflon can be injected into the paraglottic space just lateral to the true cord (Fig. 30-148). This is done to add bulk to a paralyzed cord so that the cords can better appose and thereby improve voice quality (Fig. 30-149). The procedure has also been performed to build up the resected side of a vertical hemilaryngectomy. Teflon is radiopaque and can easily be seen on CT. More recently, some otolaryngologists have used plastic preformed prostheses and other materials to add bulk to the cord and rotate the arytenoid slightly toward the midline (Fig. 30-150).[134, 135]



VIEW IMAGE

INTRODUCTION

The trachea is a flexible cylindrical tube composed of cartilaginous rings, connected by a fibromuscular membrane and lined internally by mucosa. The trachea facilitates the passage of air between the larynx and the lungs. It is positioned midline in the neck and courses slightly to the right in the upper thorax. It extends from the cricoid cartilage superiorly (at about the level of the sixth cervical vertebra) to the carina inferiorly.[1] The location of the lower end of the trachea varies with body posture, and with inspiration and expiration, and in deep inspiration the carina may descend to the level of the sixth thoracic vertebra.[2] The length of the trachea ranges from 10 to 13 cm, averaging approximately 11 cm.[2] Viewed laterally, the trachea assumes an oblique course, running from superoanterior to in-

feroposterior. In severely kyphotic patients, the trachea may have a horizontal orientation.

The degree to which the laryngeal glottis (true vocal folds) is open significantly affects airflow patterns in the trachea. The glottis has the smallest, yet the most variable, cross-sectional area of the upper respiratory tract. Air currents in the upper trachea are typically turbulent during inspiration, with a transition to more laminar flow in the middle and distal trachea. The velocity of the air stream in the distal trachea during quiet respiration is approximately 1 mm/sec.[2] During forced expiration or coughing, intrathoracic pressure becomes positive, transmural pressure differences increase, and narrowing of the intrathoracic trachea occurs. This narrowing accelerates airflow and facilitates expectoration. The airflow in the central trachea during coughing has been estimated to be approximately 250 km/hr.[3] Airflow patterns in the trachea are significantly more complicated in cases with tracheal stenosis or tracheomalacia.

Gross Anatomy/Histology

The skeleton of the trachea is composed of 16 to 20 incomplete hyaline cartilaginous rings that are bound in a tight elastic connective tissue oriented longitudinally.[1] These cartilage rings may calcify with age and two or more cartilages may unite, either partially or fully. Rarely, they may bifurcate posteriorly. The cartilage forms about two thirds of the circumference of the trachea. Because the posterior border of the trachea is formed by fibromuscular membrane, the cross-sectional shape of the trachea is that of the letter D, with the flat side posterior. The first and last cartilaginous rings differ from the rest of the tracheal rings. The first ring, located approximately 1.5 to 2 cm below the true vocal cords, is partly recessed into the broader ring of the cricoid cartilage and is the broadest of all the cartilage rings. The first ring is sometimes merged to the cricoid cartilage or to the second tracheal ring. The second, third, and fourth rings are surrounded anteriorly and laterally by the thyroid gland.[2] The last tracheal ring is thicker and broad, and on its lower border there is a triangular process that curves downward and backward between the origins of the bronchi.[4] The mucosal portions of the posterior trachea are separated from the esophagus by a thin layer of connective tissue. This region is often referred to as the common party wall, as it separates the trachea in front from the esophagus behind.

The cartilaginous rings allow the tracheal lumen to retain its patency, even in the extreme circumstances of coughing and forced expiration. The diameter of the tracheal lumen, like its length, depends on the height, age, and gender of the individual. In men, tracheal diameter ranges from 13 to 25 mm in the coronal plane and 13 to 27 mm in the sagittal plane. Tracheal diameter is slightly less in women, ranging from 10 to 21 mm in the coronal plane and 10 to 23 mm in the sagittal plane.[1] Cross-sectional area correlates most closely with height in children. With increasing age, the transverse section of the tracheal lumen successively assumes the following shapes: round, lunate, flattened, and roughly elliptical. Respiratory cycle, certain maneuvers, and body position also contribute significantly to the variation in lumen shape. During rapid deep inspiration, the thoracic portion of the trachea widens and the cervical portion narrows. The opposite pattern occurs during expiration; the extrathoracic tracheal lumen increases in size during coughing, Valsalva maneuver, or forced expirations, whereas the intrathoracic portion decreases.[2]

The trachea is lined by pseudostratified columnar epithelium that sits on an elastic lamina propria. Goblet mucous cells and small subepithelial glands that secrete onto the luminal surface are interspersed among the ciliated columnar cells.[3] There has been recent interest in studying the small intercellular bridges (tight junctions) situated between the ciliated cells.[5] These junctions may explain the observation that cilia in the respiratory tract move in a synchronous and coordinated manner. The cilia beat about 1000 times per minute, propelling the mucous lining upward toward the pharynx, from which it can be coughed up several times a day. Normally, the amount of bronchotracheal secretions expelled is quite small, averaging 10 cc over a 24 hour period.[3] Mechanical irritation by endotracheal tubes or suction devices, however, can increase this volume 10-fold. During disease states, the amount and quality of the periciliary fluid and mucous can change, interfering with the drainage and protective functions of the mucosa.

Each tracheal cartilage has a perichondrium, continuous with a dense fibrous membrane that is between adjacent cartilages and within the posterior membranous wall. The perichondrium and membrane are composed primarily of collagen with some elastin fibers. Smooth muscle fibers (trachealis muscle) are in the membrane posteriorly. Most of these muscle fibers are transverse, attaching to the free ends of the tracheal cartilages and providing alteration in the tracheal cross-sectional area. There are also longitudinal fibers. The trachealis muscle can diminish the caliber of the tracheal lumen or prevent overdistention of the trachea when there is abdominal straining prior to coughing.

Innervation and Blood Supply

The trachea is innervated by parasympathetic tracheal branches of the vagus nerve, by the recurrent laryngeal nerve, and by sympathetic nerves. The *parasympathetic pre*ganglionic nerve fibers send their axons to local ganglia in the tracheal wall. The *sympathetic post*ganglionic supply comes from both the cervical ganglia and the second through fourth thoracic ganglia. The parasympathetic *post*ganglionic as well as the sympathetic fibers innervate seromucous glands, smooth muscles, and blood vessels.[6] Tracheal smooth muscle, controlled by these autonomic nerves, contracts to narrow and stabilize the tracheal lumen, preventing excessive invagination of the dorsal membrane.

Branches of the recurrent laryngeal nerve perforate the lateral tracheal wall, providing a rich supply of sensory afferents to the inner tracheal mucosa. The trachea has a segmental blood supply, shared largely with the esophagus and derived from multiple branches of the inferior thyroidal and bronchial arteries. The inferior thyroidal arteries, as well as the extreme right intercostal artery, supply the superior portion of the trachea; branches from both the bronchial arteries and the third intercostal artery supply the inferior

Copyright © 2003, Mosby, Inc. All rights reserved.

portion of the trachea. Tracheal venous drainage is to the inferior thyroid venous plexus.

Lymphatic Drainage

Numerous lymph nodes surround the trachea, most notably in the carinal region. The major lymph node groups are the inferior tracheobronchial nodes and the right and left superior bronchial nodes. The lymphatic drainage from the proximal two thirds of the trachea passes through to the pre- and paratracheal lymph nodes (level VI), eventually draining into the lower jugular nodes (level IV).

The pattern of tracheal lymph node drainage is important for the radiologist to be aware of for the purpose of lung cancer staging. For example, left apical lung cancers tend to drain to aortopulmonary window nodes rather than to hilar and paratracheal nodes. Lower-lobe cancers are more likely to drain to hilar nodes, followed in frequency by subcarinal and paratracheal region nodes. Staging of lung cancer, according to the American Thoracic Association, is based largely on knowledge of the nodal stations of the mediastinum—particularly the paratracheal nodes.[7]

Surrounding Anatomic Structures

The trachea is surrounded by the esophagus, thyroid gland, lungs, aorta, vagus nerves, recurrent laryngeal nerves, and azygos veins. It moves vertically with neck extension or flexion relative to these structures. The esophagus is positioned directly posterior to the cervical portion of the trachea and typically extends slightly to the left of the intrathoracic portion. Foreign bodies or tumors of the esophagus may therefore manifest with airway symptoms due to compression of the posterior membranous trachea (common party wall). On plain film radiography, the thin tracheal wall (1 to 2 mm) is well defined by air in the tracheal lumen, as well as by the adjacent mediastinal fat. As mentioned, cartilaginous calcification is increasingly common with age, especially in women.[1]

The vagus nerve exits the skull base at the jugular foramen and courses inferiorly along the posterolateral aspect of the carotid artery. On the left, the recurrent laryngeal nerve loops from anterior to posterior under the aortic arch, at the ductus arteriosus, where it begins its ascent. On the right, it similarly loops under the subclavian artery. The recurrent laryngeal nerves ascend bilaterally in the tracheoesophageal groove.[8] The course of the left recurrent laryngeal nerve is of clinical interest for several reasons. An aneurysm of the aorta, or another mass lesion, can apply traction to the nerve, resulting in recurrent laryngeal nerve palsy. A very rare mechanism of recurrent laryngeal nerve palsy relates to severe coughing spasms, during which the heart and great vessels can create traction on the left recurrent laryngeal nerve sufficient to cause neuropraxia.

Under normal conditions, the aortic arch courses anterior to the intrathoracic trachea, along the left and dorsally. The most fixed point of the trachea is in this region. The descending aorta may cause a slight impression at the lower left trachea. The innominate (brachiocephalic) artery crosses anterior to the trachea and can cause an indentation, particularly in infants. The azygos vein crosses the distal dorsal trachea toward the right tracheobronchial angle, and rarely produces an indentation. In infancy, the innominate vein lies anterior to the lower cervical trachea; in adulthood, this vein is intrathoracic.[9, 10]

RADIOGRAPHIC EVALUATION OF THE TRACHEA

The radiologic evaluation of the trachea includes plain films (both lateral neck and anteroposterior high-kilovoltage views), tomograms, computed tomography (CT), and magnetic resonance (MR) imaging.[11] CT is of great value in assessing the spectrum of disease that affects the trachea and has largely become the imaging modality of choice, especially now that two-dimensional and three-dimensional reformatted views can be routinely obtained through image postprocessing. Airway fluoroscopy, barium studies of the esophagus, angiography of vascular lesions, and conventional tomography all may play a part in the evaluation of tracheal pathology.

Plain Radiographs

Plain chest radiography in the posteroanterior (PA) and lateral projections is the most frequently used imaging tool for patient screening (Fig. 31-1). A high-kilovoltage (140 kVp) technique is preferred because it reduces the visibility of the bony thorax and improves imaging of the various mediastinal structures. There is considerable overlap of the trachea with the mediastinum and bony thorax, making many tracheal lesions difficult to visualize. The lateral neck film, obtained with the head slightly hyperextended, is useful for studying the cervical trachea. Flexion of the neck, especially in children, may cause buckling of the trachea, resulting in the appearance of a prevertebral ''pseudomass.'' The majority of patients with tracheal pathology require further imaging evaluation with CT scanning.

CT Scanning

CT has largely become the imaging modality of choice for most tracheal lesions. It allows direct visualization of the cross-sectional tracheal airway, and can be used to determine the size, extent, and attenuation value of a lesion. Helical (spiral) CT, with 1 to 1.5 mm thin sections, allows high-quality multiplanar reconstruction, facilitating detailed evaluation of disorders such as tracheal stenosis and tumors. CT is helpful in the evaluation of tracheal neoplasms that invade the mediastinum, as well as in the evaluation of other lesions such as goiters or vascular rings that may compress the trachea. CT can also be used to determine accurately the length of a tracheal lesion relative to the endoscopic reference points of either the larynx or the carina. CT can identify enlarged lymph nodes along the tracheal wall and in the mediastinum. It can also identify calcific or fatty

VIEW IMAGE

FIGURE 31-1 Large cell carcinoma. Posteroanterior (**A**) and lateral (**B**) views of the chest demonstrate a large, broad-based endoluminal mass arising from the right lateral tracheal wall (*arrow* in **A**).

densities, as well as vascular enhancement of tumors or aneurysms. Abnormal collapsibility of the trachea (i.e., tracheomalacia) can be identified by paired inspiratory/expiratory CT scans. CT is also useful in directing surgical or fine needle aspiration (FNA) biopsy of more aggressive lesions. Finally, spiral CT angiography with 3D reconstruction methods (Fig. 31-2) may reveal vascular anomalies affecting the tracheal lumen.

Congenital lesions affecting the trachea typically require a chest X-ray as a screening examination, followed by MR imaging or spiral CT to identify vascular anomalies or mediastinal masses. Inspiratory and expiratory CT can be used to investigate tracheal stenosis. CT is also the imaging modality of choice to investigate tracheal stenosis due to intubation or tracheotomy tubes. Finally, spiral CT is considered a valuable tool in the investigation and treatment planning of all lesions that will undergo endoscopic therapy.[12]

MR Imaging

MR imaging can be utilized in the assessment of tracheal stenosis and tumors. However, the current role of MR imaging is quite limited, as its spatial resolution does not permit adequate evaluation of the segmental bronchi and the longer scan times allow for respiratory motion image degradation. MR imaging, however, can depict a moderate degree of anatomic detail *without* employing ionizing radiation or iodinated intravenous contrast medium.[13] T1-weighted sequences demonstrate the anatomy of the trachea and surrounding structures in detail, whereas T2-weighted sequences add to the characterization of lesion signal differences, such as differentiation of cystic from solid masses. MR imaging is particularly useful in cases of tracheal compression by vascular rings and slings or by other mediastinal masses.

Virtual Bronchoscopy

Three-dimensional reconstruction of helical CT data permits navigation through the tracheobronchial tree via real-time simulated bronchoscopy. Recent advances in computer technology allow faster imaging times with a decrease in radiation dose and motion artifact. Unlike conventional fiberoptic bronchoscopy, virtual broncoscopy (VB) permits visualization of the relationship between an airway lesion and the surrounding mediastinal structures as well as airway patency beyond a stenosis. In addition, the viewer can repeatedly navigate through the airway without adverse consequences to the patient. The level of obstruction and the width and length of an airway stenosis can easily be measured. This information can be used in preoperative planning for resection of tracheal tumors or for palliative stent placement. VB also appears to be useful in imaging pediatric disorders such as vascular rings, tracheomalacia, and congenital tracheoesophageal fistula.

Despite initial enthusiasm, however, the practical application of volume rendering techniques remains in question.

FIGURE 31-2 Postpneumonectomy syndrome. A 28-year-old female with congenital hypoplasia of the right lung who underwent right pneumonectomy following recurrent pulmonary infections. Several months after surgery, the patient developed severe shortness of breath. **A**, Contrast-enhanced axial CT scan of the chest shows right mediastinal shift, with herniation of the left lung into the right hemithorax (*upper row*). Note the compression of the proximal left mainstem bronchus between the transverse aorta and the vertebral body (*arrow, left upper row*). The mediastinal shift was corrected by insertion of saline breast implants (*short arrows, lower rows*) into the right pneumonectomy space. Following this, the trachea was midline and the compression of the left mainstem bronchus was resolved. **B**, Three-dimensional reconstructions from the dataset in **A** before and after placement of saline implants.

Conventional axial CT and virtual images are equally accurate in estimating the maximal luminal diameter and cross-sectional area of the central airways. Sufficient clinical data are not yet available to judge whether VB offers a true benefit to patients over that of the already high predictive values of conventional CT. Although VB may not offer improved diagnostic accuracy, it is a promising technique that tends to enhance the overall understanding of a disease process, and it will likely prove useful in surgical planning and communication of imaging results to referring clinicians (Figs. 31-2B, 31-3, and 31-4).[14, 15]

PATHOLOGIC CONDITIONS

Clinical detection of tracheal disease is notoriously difficult. With healthy lungs, occlusion of more than 75% of the tracheal lumen is necessary to cause symptoms of airway obstruction at rest.[1] Occlusion of about 50% of the cross-sectional tracheal airway is needed to produce symptoms of dyspnea on exertion. As a result, early identification of tracheal pathology is unusual. Symptoms such as hemoptysis, wheezing, or coughing may not manifest until disease is advanced. Radiographically, the trachea is often a blind spot on conventional X-rays, with lesions not identified until they are quite large. CT is the standard method for imaging a patient who has clinical symptoms suggesting tracheal obstruction.

Congenital Abnormalities

The trachea can be affected by an intrinsic anomaly isolated to the trachea or by an anomaly of the contiguous soft tissues that causes external pressure on the airway. Some abnormalities, such as stenosis or tracheomalacia, can occur as an isolated phenomenon or in conjunction with a second abnormality.

Tracheomalacia

Tracheomalacia is defined as collapse of the trachea on expiration, resulting in more than 10% to 20% obstruction of the airway. It is characterized by abnormal flaccidity of the trachea during the respiratory cycle, leading to abnormal collapse of the thoracic tracheal segment on expiration. Weakness of the tracheal wall results from softening of the supporting cartilage, with abnormal widening of the posterior membranous (noncartilaginous) wall. Frequently,

VIEW IMAGE

the anterior and posterior tracheal walls move closer together during respiration and coughing, reducing the intraluminal diameter (Figs. 31-5 and 31-6). The unsupported posterior wall may balloon anteriorly into the airway. Patients complain of inspiratory and/or expiratory stridor, wheezing, barking cough, or recurrent respiratory infections. The triad of an anterior bulging posterior tracheal wall, narrowed anteroposterior tracheal luminal diameter, and widened posterior membranous tracheal wall is typical. Tracheomalacia is the major cause of respiratory difficulty following repair of a tracheoesophageal fistula.

Patients with tracheomalacia may present with minimal symptoms or with severe, life-threatening airway obstruction. In children, the tracheobronchial tree is more collapsible than in adults. Hence, the classic expiratory stridor of tracheomalacia may be present at birth. Tracheomalacia can be categorized into either primary intrinsic or secondary extrinsic forms. Primary tracheomalacia is caused by an inherent defect of the tracheal cartilaginous rings. In secondary tracheomalacia, airway collapse on expiration may be due to extrinsic tracheal compression by a mass or vascular structure, as well as by conditions causing intrinsic weakness of the tracheobronchial structures. Secondary tracheomalacia may be associated with conditions such as tracheoesophageal fistula, laryngotracheal esophageal cleft, cardiac abnormalities, or vascular compression. Localized tracheomalacia is associated with tracheotomy.

Airway fluoroscopy, combined with a barium swallow, can demonstrate evidence of vascular compression. Rigid bronchoscopy is helpful for evaluating the degree of tracheobronchial tree collapse, as well as for documenting the presence of associated congenital airway anomalies. Cine CT imaging and 3D imaging of the trachea during inspiration and expiration are newer modalities that are likely to prove useful.[16] In cases of suspected vascular compression or cardiac anomalies contributing to tracheomalacia, MR imaging and echocardiography can also be performed.

Mild cases of primary tracheomalacia often do not require treatment, because they often resolve within the first 1 to 2 years of life. In cases of severe airway obstruction with tracheal collapse, tracheostomy with long-term positive airway pressure ventilation may be indicated. Surgical decompression of the trachea may lead to significant improvement in cases of vascular compression. Different surgical procedures have been developed for the treatment of tracheomalacia, with various degrees of success. These procedures include placement of internal and external stents, segmental resection, and cartilage grafting to the trachea.

Congenital Stenosis (Subglottic/Tracheal)

Congenital stenosis is an uncommon abnormality that usually is associated with other major or minor anomalies of the respiratory tract skeleton or other organ systems.

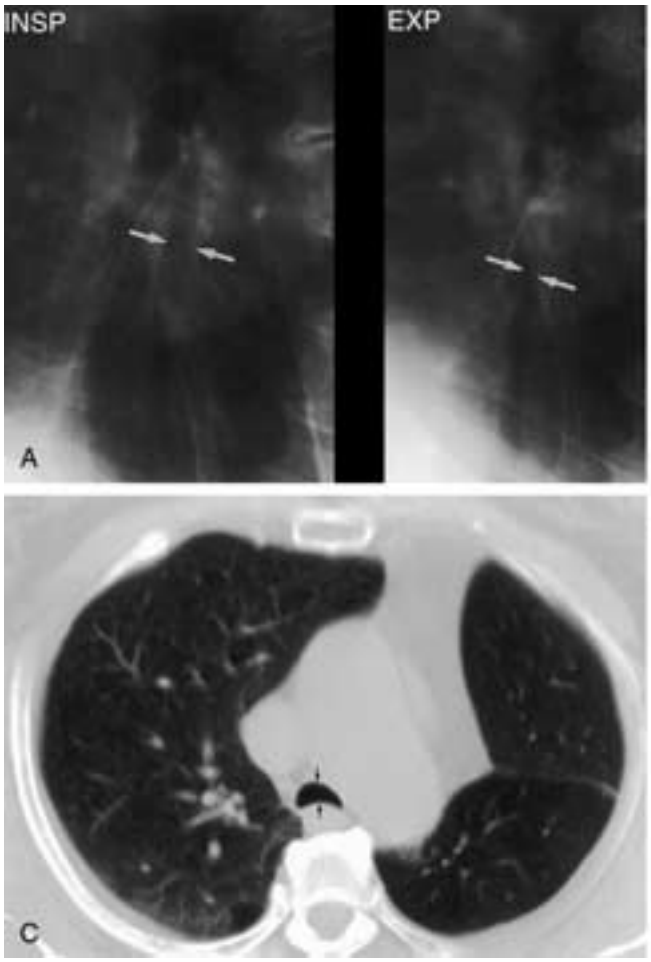

FIGURE 31-5 Tracheomalacia. **A**, Fluoroscopic evaluation of this 71- year-old man with a 5-year history of progressive stridor demonstrates diffuse narrowing of the trachea with expiration. The luminal diameter of the trachea was reduced by approximately 50% (*arrows*). Nonenhanced axial CT scan, filmed in lung windows, again demonstrates tracheal narrowing on expiration (**C**, *arrows*) compared with inspiration (**B**, *arrows*).

VIEW IMAGE

Commonly, there is an association with the H-type tracheoesophageal fistula, pulmonary hypoplasia, and a vascular sling. The affected segment of trachea has rigid walls with a narrowed lumen. The stenotic segment can be focal or affect the entire trachea, extending into the mainstem bronchi. Cartilages can be complete rigid rings.

Clinically, presentation occurs within the first weeks or months of life. Although segmental resection has been reported, it is rarely feasible due to the length of the stenotic segment. Most cases are treated conservatively and the patient may live with the stenosis, the tracheal lumen growing larger as the patient ages. However, approximately one half of these patients die either of the stenosis and associated pulmonary infections or of the major congenital anomalies associated with it.

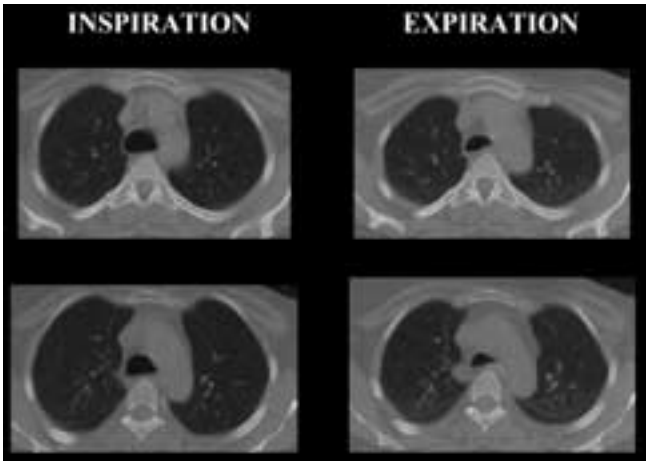

FIGURE 31-6 Tracheomalacia. A 62-year-old female with an increasingly loud, uncontrollable cough. Inspiratory and expiratory axial CT images of the upper thorax demonstrate a 44% reduction in the anteroposterior tracheal diameter on expiration. Both flexible and rigid bronchoscopy revealed a flattened, lax trachea with a redundant membranous wall.

Tracheal Bronchus

The term *tracheal bronchus* refers to any well-defined airway that arises from the trachea above the level of the carina. Although this anatomic configuration is normal for many mammals, it represents an anomaly in humans and is found in only 0.25% to 1% of the population.[17] Although the anomalous bronchus typically arises from the tracheal wall less than 2 cm above the tracheal bifurcation, it may arise as high as 6 cm above the carina. The tracheal bronchus originates more frequently from the right, rather than from the left, in which case it supplies a variable portion of the medial or apical right upper lobe (Fig. 31-7). The incidence of this anomaly is greatest in patients with other coexisting congenital malformations such as congenital tracheobronchial stenosis, aberrant pulmonary artery, Down's syn-

FIGURE 31-7 Right tracheal bronchus. Contiguous axial CT images through the upper thorax demonstrate an anomalous right upper lobe bronchus (*arrow*) arising directly from the trachea in this patient with metastatic bladder carcinoma.

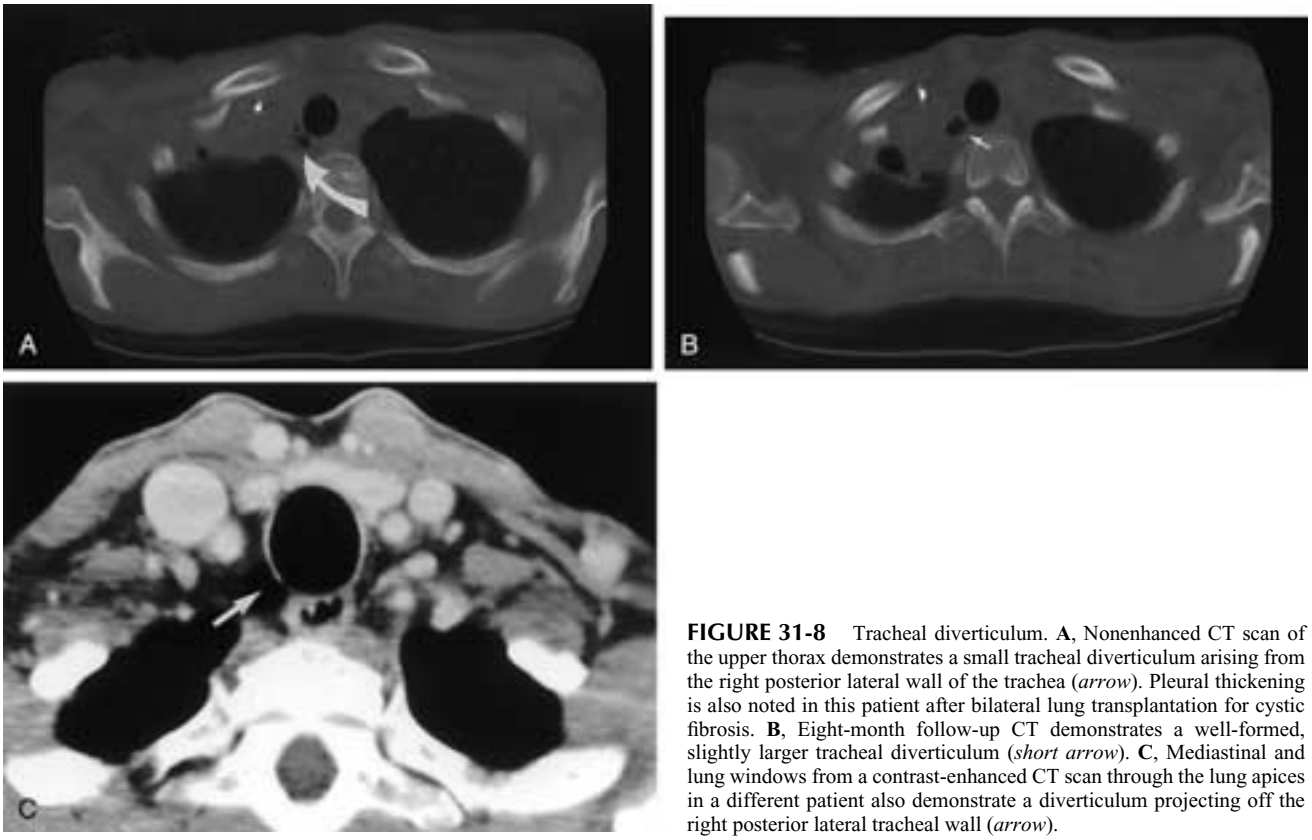
drome, right aortic arch, or lung hypoplasia.[18] Although frequently asymptomatic, patients with tracheal bronchus may develop recurrent infections or bronchiectasis due to stenosis at the origin of the bronchus. Pooling of secretions, and/or obstruction of the orifice of the tracheal bronchus by an endotracheal tube, may cause atelectasis. Thus, it is important to keep this airway anomaly in mind when caring for patients with unusual sensitivity to endotracheal tube (ETT) position or with chronic right upper lobe atelectasis.

Tracheal Diverticula (Tracheocele)

A tracheocele is an outpouching or diverticulum of the posterolateral wall of the trachea.[19] Tracheocele is a rare condition that results from muscular weakness of the tracheal muscle. Wide-mouthed tracheoceles are likely acquired, whereas narrow-mouthed tracheoceles are likely congenital in origin (Fig. 31-8). Tracheoceles may be transient, seen only during periods of increased intratracheal pressure. Occasionally, on chest radiographs, they may present as thin-walled paratracheal air-filled cavities, with or without air-fluid levels. CT best displays these lesions and can provide 3D imaging of their size and extent, along with volumetric reconstruction. Although tracheoceles tend to be asymptomatic, they may become quite capacious and accumulate debris. This debris may spill into the lungs and cause pneumonia.

Tracheoesophageal Fistula

Tracheoesophageal fistula (TEF) is a common congenital anomaly, with an average frequency of 1 in 3000 to 4000 births, and is often associated with esophageal atresia.[20] TEF can exist in a number of forms (Fig. 31-9), the most common configuration being that of a proximal esophageal atresia with a distal TEF (Figs. 31-10 and 31-11). This anomaly may be associated with severe neonatal respiratory distress, often necessitating immediate tracheostomy. Approximately 85% of neonates with this TEF present within the first 24 hours of life with excessive mucus production, cough, choking, and cyanosis associated with feeding.[21] In approximately half of the patients with TEF and esophageal atresia, more than one fistula may be present. Associated



VIEW IMAGE

anomalies involving the cardiovascular, gastrointestinal, renal, or central nervous system may also be present.[22] Patients with normal birth weight and no other congenital malformations have the highest rates of survival. The overall survival rate is approximately 80%.[2]

H-type TEF, without esophageal atresia, is a less common type of TEF that has more subtle clinical manifestations and is characteristically associated with gastroesophageal reflux. Symptoms may include excessive oral secretions, respiratory distress, or immediate regurgitation of feedings; intermittent dysphagia and choking may also be present. The diagnosis of this type of TEF may be delayed until adulthood. Patients with H-type TEF usually have no associated congenital anomalies or can have congenital tracheal stenosis.

TEF *with* esophageal atresia is easily diagnosed by the failure to pass a radiopaque nasogastric tube into the stomach. The tube coils in the proximal esophageal pouch and can be seen on routine chest radiography or after the instillation of a small amount of water-soluble contrast material (Fig. 31-10B). Associated aspiration pneumonia may be present. Tracheomalacia may develop at the fistula site, usually resolves by the age of 2 years, and is best diagnosed by collapse of the airway structures on direct fluoroscopy. Patients with esophageal atresia and *both* proximal and distal TEFs (rare) may have gaseous distention of the gastrointestinal tract with aspiration pneumonia. This diagnosis can be confirmed by contrast studies. Barium swallow with fluoroscopy is typically employed to diagnose H-type fistulas. Cine-esophagography (cinefluorography or fluoroscopy with videotaping) can assist in differentiating TEF from simple laryngeal aspiration. Combined bronchoscopy and esophagoscopy have also been useful in increasing the ability to diagnose TEF. Surgery is the treatment of choice.[23]

Vascular Rings and Slings

Vascular anomalies of the great vessels include ''rings'' and ''slings''[11, 24, 25] (see also Chapter 29). Airway compression by vascular anomalies may be congenital or acquired. In children, vascular impressions on the trachea are generally congenital and may cause a spectrum of symptoms, from minimal to severe airway compression requiring intervention. Vascular compression syndromes in

Copyright © 2003, Mosby, Inc. All rights reserved.

adults are usually secondary to acquired aneurysmal dilatation of the great vessels. The radiologic evaluation of children with respiratory symptoms possibly due to vascular compression should include barium study of the esophagus, which is often affected along with the trachea by vascular rings. Contrast-enhanced CT angiography with 3D reconstructions and multiplanar reformatting is an excellent method of evaluating patients with complex great vessel anomalies. Alternatively, MR imaging can provide images of the vessels and the surrounding soft tissues.

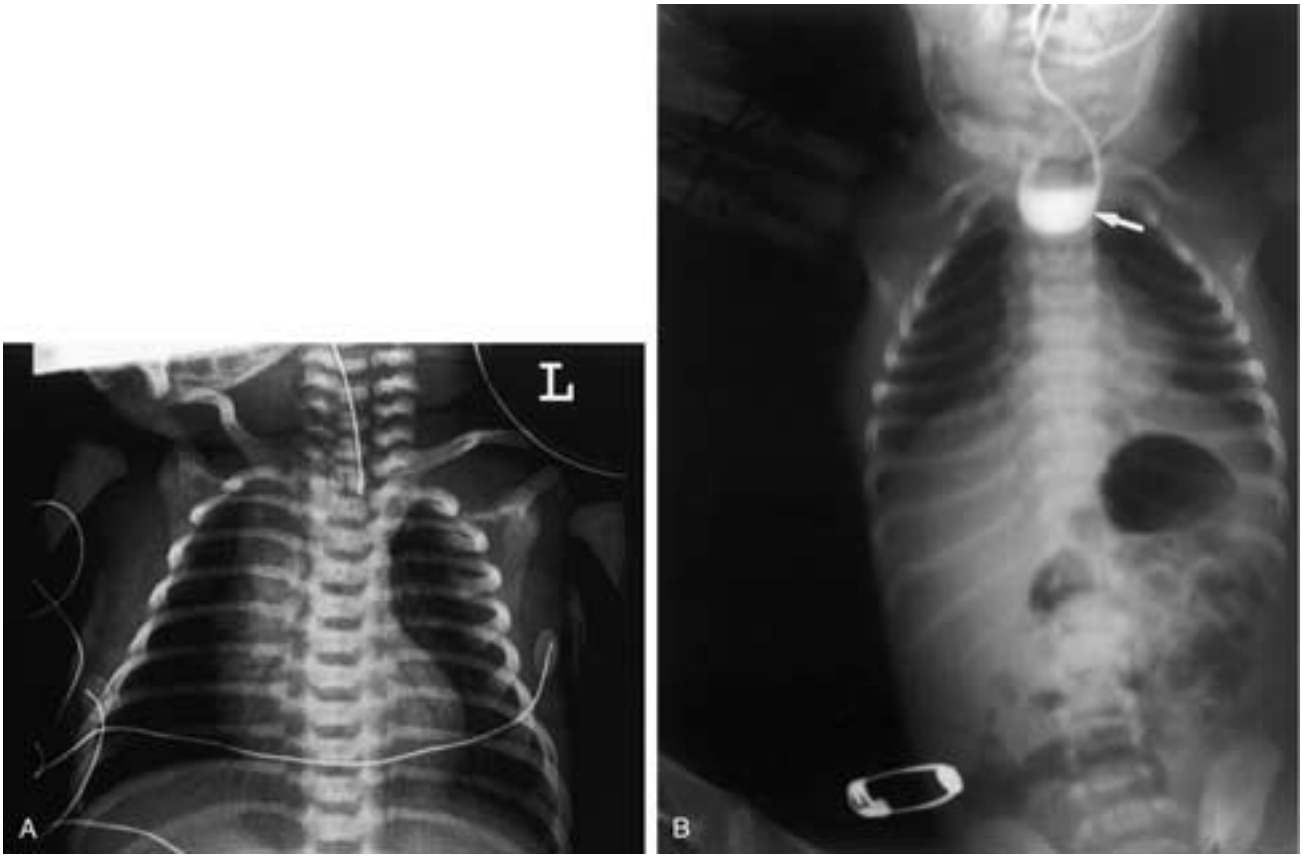
Vascular *rings* are anomalies that completely encircle the trachea and esophagus, causing airway compression. The most common vascular ring is a double aortic arch (Fig. 31-12).[26] Patients with double aortic arch typically present early in life with airway obstruction and often require early surgical intervention. Another, less constricting, vascular ring is a right aortic arch with descending right aorta associated with an aberrant left subclavian artery and persistent ligamentum arteriosum. In both types of vascular ring, there is circumferential tracheal and esophageal indentation. Other findings include left-sided and anterior displacement of the distal trachea. Barium studies show a characteristic dorsal and left-sided impression on the esophagus.

Vascular *slings* are noncircumferential vascular anomalies that may also cause airway compromise. These anomalies may lead to significant morbidity and occasional mortality.[26] However, vascular rings often cause more severe airway symptoms than slings.[23] In the pulmonary artery sling, the left pulmonary artery originates from the right pulmonary artery and then passes between the trachea and esophagus to reach the left lung. The trachea is compressed from posteriorly, and there is an impression on the anterior esophagus seen at barium swallow.

Anterior impression on the trachea by the innominate artery in infants and children is much more common than compression by an aberrant left subclavian artery.[27] Although most patients develop symptoms during the first year of life, some reported cases have presented as late as 15 years of age. Symptoms include expiratory stridor, recurrent cough, apnea, and recurrent infection. Rigid bronchoscopy may establish the definitive diagnosis. In severe cases of airway obstruction, surgical intervention is warranted.

Diffuse Disorders of the Trachea (Nonneoplastic)

Various infections and inflammations involve the tracheal wall. They may cause infiltration with narrowing or, less commonly, widening of the trachea.



VIEW IMAGE

Conditions Causing Narrowing of the Trachea

Infection

Laryngotracheobronchitis (croup) is the most common infection of the trachea. Croup is a disease of infants and young children, with a peak incidence between the ages of 6 months and 3 years.[28] Parainfluenza and respiratory syncytial virus are the most common agents. Clinical symptoms include a ''barking'' cough and intermittent inspiratory stridor. Although typically infection involves the entire airway, critical narrowing usually occurs at the proximal 2 cm of the trachea. At this level, the tracheal mucosa is relatively loose, and therefore susceptible to edema and luminal narrowing. Anteroposterior radiographs demonstrate loss of the lateral convexities of the subglottic trachea, with luminal narrowing. This narrowing produces an inverted V configuration, with the point of the V at the level of the inferior margin of the true vocal cords. This subglottic narrowing is accentuated during expiration. It should be kept in mind that radiologic evaluation is not performed to *diagnose* croup, but to *exclude* other causes of stridor such as epiglottitis.

Bacterial tracheitis is an atypical form of croup, with a clinical picture more closely resembling that of epiglottitis.[29–31] The organisms most commonly involved are *Staphylococcus aureus*, group A beta-hemolytic streptococci, and *Haemophilus influenzae* type b.[29–31] Although early symptoms may mimic viral croup, they do not resolve with conventional medical therapies. The subsequent course is typically severe, with high fever, stridor, and dyspnea with production of purulent sputum. Intubation or tracheotomy may be required to prevent obstruction by purulent exudate. The primary focus of inflammation/obstruction is subglottic, with sparing of the epiglottis and supraglottic structures. The definitive diagnosis of *bacterial* tracheitis can be made by direct inspection of the purulent exudate, which is not present in viral croup. Laryngoscopy and bronchoscopy can be therapeutic; microbiologic tests are important in confirming the etiologic agent and in selecting or modifying antibiotic therapy.

Tuberculosis

Tuberculous tracheitis is rare and is usually associated with active pulmonary tuberculosis.[32, 33] The infection typically involves the distal trachea, where inflammation results in irregular circumferential tracheal wall thickening, leading to narrowing or even obstruction. Areas of necrosis and ulcerations may develop. Mediastinal and hilar lymphadenopathy are usually present. Fibrosis from chronic inflammation can lead to segmental stenosis of the trachea and bronchi. Erosion into adjacent mediastinal structures can lead to the development of a tracheoesophageal fistula or to severe hemorrhage from vascular invasion. Erosion of calcified lymph nodes into the airway can lead to expectoration of broncholiths.[34]

Histoplasmosis

Like tuberculosis, histoplasmosis can result in lymph node calcification. Granulomatous lesions arise outside the airways and tend to erode into the lumen. As with

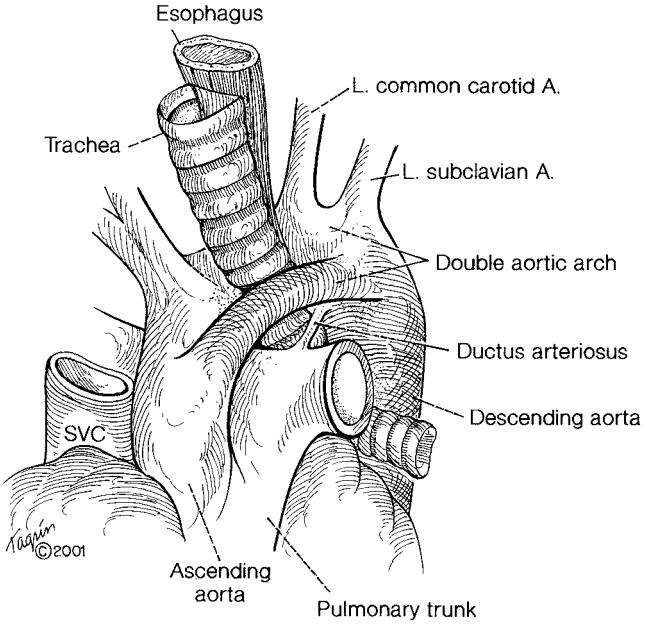

FIGURE 31-12 Double aortic arch.

VIEW IMAGE

Copyright © 2003, Mosby, Inc. All rights reserved.

tuberculosis, intraluminal extension is associated with hemoptysis and expectoration of broncholiths.

Fibrosing mediastinitis is a fibroinflammatory infiltrative process most commonly attributed to histoplasmosis.[25, 35–38] Large masses of fibrous tissue can form in the mediastinum. The accumulated fibrous tissue can squeeze the trachea or bronchi, resulting in long areas of airway narrowing. The patient can present with cough, hemoptysis, or difficulty breathing. The pulmonary arteries and veins can also be narrowed, resulting in significant vascular compromise. The lesions usually calcify and can have low signal intensity on T2-weighted images. These features may help differentiate the lesion from an invasive malignancy. Fibrosing mediastinitis has also been associated with tuberculosis, lymphatic obstruction, and methylsergide.

CT is the best single technique for diagnosing and assessing the severity of mediastinal fibrosis, as well as for evaluating tracheal luminal narrowing. CT studies performed both prior to and following the administration of intravenous contrast may be helpful in differentiating calcified lymph nodes from enhancing vessels.

Mediastinal granuloma is closely related to fibrosing mediastinitis. This term describes a well-demarcated mass of lymph nodes located in the mediastinum. It is commonly discovered as a mass lesion on routine chest radiography, typically in the right paratracheal or hilar regions. Mediastinal granuloma is often encapsulated and asymptomatic. If symptoms are present, they relate to compression of various mediastinal structures, including the major veins, tracheobronchial tree, esophagus, recurrent laryngeal nerves, pulmonary arteries, and heart. Narrowing of the tracheobronchial tree typically involves the major bronchi, with less frequent involvement of the distal trachea. Surgery is often indicated for diagnostic reasons (e.g., to exclude lymphoma) or for relief of specific symptoms.[39]

Relapsing Polychondritis

Relapsing polychondritis is a rare systemic disease characterized by recurrent episodes of inflammation, fragmentation, and fibrosis of cartilage tissue including the ears, nose, joints, and airways. Its incidence peaks in the fifth decade of life, and there is no sex predilection.[39] The upper airways (larynx and trachea) are affected in more than half of the patients. Tracheal involvement occurs late in the course of the disease. Diffuse tracheal inflammation is limited to the cartilage and perichondrium, with sparing of the mucosa and submucosa.[40] Respiratory manifestations are often severe and may be life-threatening.[41] Cardiovascular manifestations are present in one third of patients.

CT usually shows tracheal narrowing with diffuse wall thickening limited to the anterior and lateral tracheal walls, sparing of the posterior membrane, and narrowing of the lumen.[1] When calcification is seen within the tracheobronchial wall, the cartilage may appear thicker than normal. Both the inner and outer borders of the thickened tracheal wall are smooth, and areas of tracheomalacia may coexist. Fiberoptic bronchoscopy can be useful for both direct visualization and biopsy.

Granulomatous Disease of the Trachea

Wegener's granulomatosis is a hypersensitivity necrotizing granulomatous vasculitis that can involve the upper and lower respiratory tracts and may result in tracheal stenosis. It typically occurs in adults, with a peak incidence in the fourth and fifth decades of life.[42] Two or more organ systems may be affected simultaneously. Pulmonary and renal involvement together occurs in more than two thirds of cases.[43] The kidneys are frequently affected, as are other organs such as the skin, nervous system, eyes, ears, and heart. Tracheal involvement typically manifests as diffuse or focal tracheobronchial narrowing.[44] Although destruction of cartilage may result, malacia is not typical. Dyspnea and progressive airway obstruction develop over months or years following the initial diagnosis of the disease.

CT features include circumferential wall thickening with narrowing of the tracheal lumen. Enlarged, abnormally calcified tracheal cartilage may also be present.[44] Mediastinal and hilar lymphadenopathy are rare thoracic manifestations of Wegener's granulomatosis.[45]

Sarcoidosis

Sarcoidosis is a systemic granulomatous disease of unknown etiology. Involvement of the lungs, mediastinal lymph nodes, eyes, and skin is common. On rare occasion, the trachea can be involved.[46] Sarcoidosis can lead to diffuse narrowing of the trachea and main bronchi and can cause upper-airway obstruction (Fig. 31-13). Dyspnea and cough usually result from extensive fibrosis, which causes distortion and narrowing of the airway. Bronchial compression by mediastinal lymph nodes and airway hyperreactivity, presumably due to inflammation, contribute to the symptoms. While obstruction of the lower airway by granulomatous infiltration and chronic pulmonary fibrosis is common, tracheal stenosis is rare.

Amyloidosis

Amyloid infiltration of the airways may occur as an isolated phenomenon or as part of a diffuse systemic disease. The focal form of amyloidosis, in which amyloid deposits in a tumor-like fashion, is usually limited to one organ or organ system. This form can be found in approximately 10% of cases.[47] Primary solitary amyloidosis of the trachea is very rare and has no features to differentiate it from other tumors.[48] Deposition of amyloid in the submucosal and muscular layers of the trachea and bronchi can lead to tracheal narrowing and ulceration.

Tracheobronchial amyloidosis can involve the bronchial tree either as a single pseudotumorous mass or in a diffuse form.[49] The diffuse form is more frequent and is characterized by extensive subepithelial amyloid deposits. The elevated mucosa, which forms ridges and nodules (approximately 0.5 to 5 cm in diameter) that may calcify, can narrow the tracheal lumen.[2] Plain film radiographs and CT scanning demonstrate focal or diffuse narrowing of the trachea and bronchi (Fig. 31-14). The nodular form of tracheobronchial amyloid may appear on CT as a focal mass, partially or completely occluding the airway. There is often infiltration of adjacent peritracheal or bronchial tissue, frequently with calcified foci. In this form, it may mimic the appearance of both benign and malignant tracheal tumors. Depending on the size and calcification of the deposition, hemoptysis or airway obstruction may occur, ultimately resulting in atelectasis or recurrent pulmonary infection. Resection with a carbon dioxide laser and repeated bronchoscopic resection are successful methods of treatment.[39]

Tracheopathia Osteochondroplastica

Submucosal cartilaginous and/or osseous nodules characterize this rare benign disease of the trachea. These nodules project into the lumen, causing considerable deformity. The lesions vary in size and are located mainly in the anterolateral tracheal wall, sparing the posterior membranous portion of the wall.[2] Most often, these lesions involve the inferior two thirds of the trachea, and frequently extend into the proximal portions of the major bronchi.[2]

The disease tends to occur in patients over 50 years of age, with equal frequency in males and females.[32] Patients may be asymptomatic but often present with cough, dyspnea, hemoptysis, and recurrent pneumonia. The etiology is unknown, although it has been suggested that tracheopathia osteochondroplastica develops secondary to metaplasia of the submucosal connective tissue.[32]

Chest radiographs may show tracheal scalloping, calcified nodules, or diffuse narrowing of the trachea. The tracheal wall may be calcified. CT scan can reveal nodular thickening and irregularity of the anterior and lateral walls of the trachea, with punctate calcification from the level of the thoracic inlet to the carina.[50, 51] Small calcified nodules along the inner aspect of the tracheal cartilage protrude into the tracheal lumen (Fig. 31-15). The differential diagnosis includes physiologic calcification of the tracheobronchial tree (in the elderly), tracheal amyloidosis, inflammatory conditions, and diffuse tumorous processes. Pulmonary function studies may indicate some degree of tracheal obstruction. Many patients with tracheopathia osteochondroplastica have a ''saber sheath'' tracheal deformity in the absence of obstructive lung disease.

Saber-Sheath Trachea

Saber sheath is a common variation of tracheal morphology that typically affects male smokers with chronic obstructive pulmonary disease.[44] Some patients with tracheopathia osteochondroplastica may present with this deformity.

The saber-sheath trachea is characterized by a marked decrease in the transverse diameter of the intrathoracic trachea associated with an increase in its sagittal diameter. The extrathoracic trachea is normal in these cases. In its earliest stages, narrowing is visible only at the thoracic inlet.[44] In more advanced cases, the stenosis involves all or part of the intrathoracic trachea. Saber-sheath trachea is clearly demonstrated on a CT scan obtained during forced expiration or a Valsalva maneuver. Inward bowing or displacement of the lateral tracheal walls is present and is due to weakness of the tracheal cartilages.[52]

Diffuse Conditions Causing Widening of the Trachea

Tracheobronchomegaly (Mounier-Kuhn Syndrome)

This rare condition, characterized by marked dilatation of the trachea and mainstem bronchi, is associated with atrophy of the cartilaginous, muscular, and elastic components of the tracheal wall. Patients commonly have associated bronchiectasis, with a history of recurrent pneumonia. The disease is most commonly diagnosed in males in their third to fourth decades of life. Patients typically have a long-standing, unusually loud, productive cough, with hoarseness and dyspnea. There is an association with other primary connective tissue disorders, such as Ehlers-Danlos syndrome and acquired cutis laxa.

The diagnosis of tracheobronchomegaly is made primarily by radiologic evaluation. On plain chest radiographs the trachea appears enlarged, and bronchiectasis is present. CT findings include tracheomegaly, with thinning of the tracheal wall, and a diameter of more than 3 cm below the level of the aortic arch or more than 2 cm above the level of the arch (Fig. 31-16). Tracheal scalloping or frank diverticulosis can also be present, although difficult to appreciate on cross-sectional imaging. Three-dimensional reconstructions

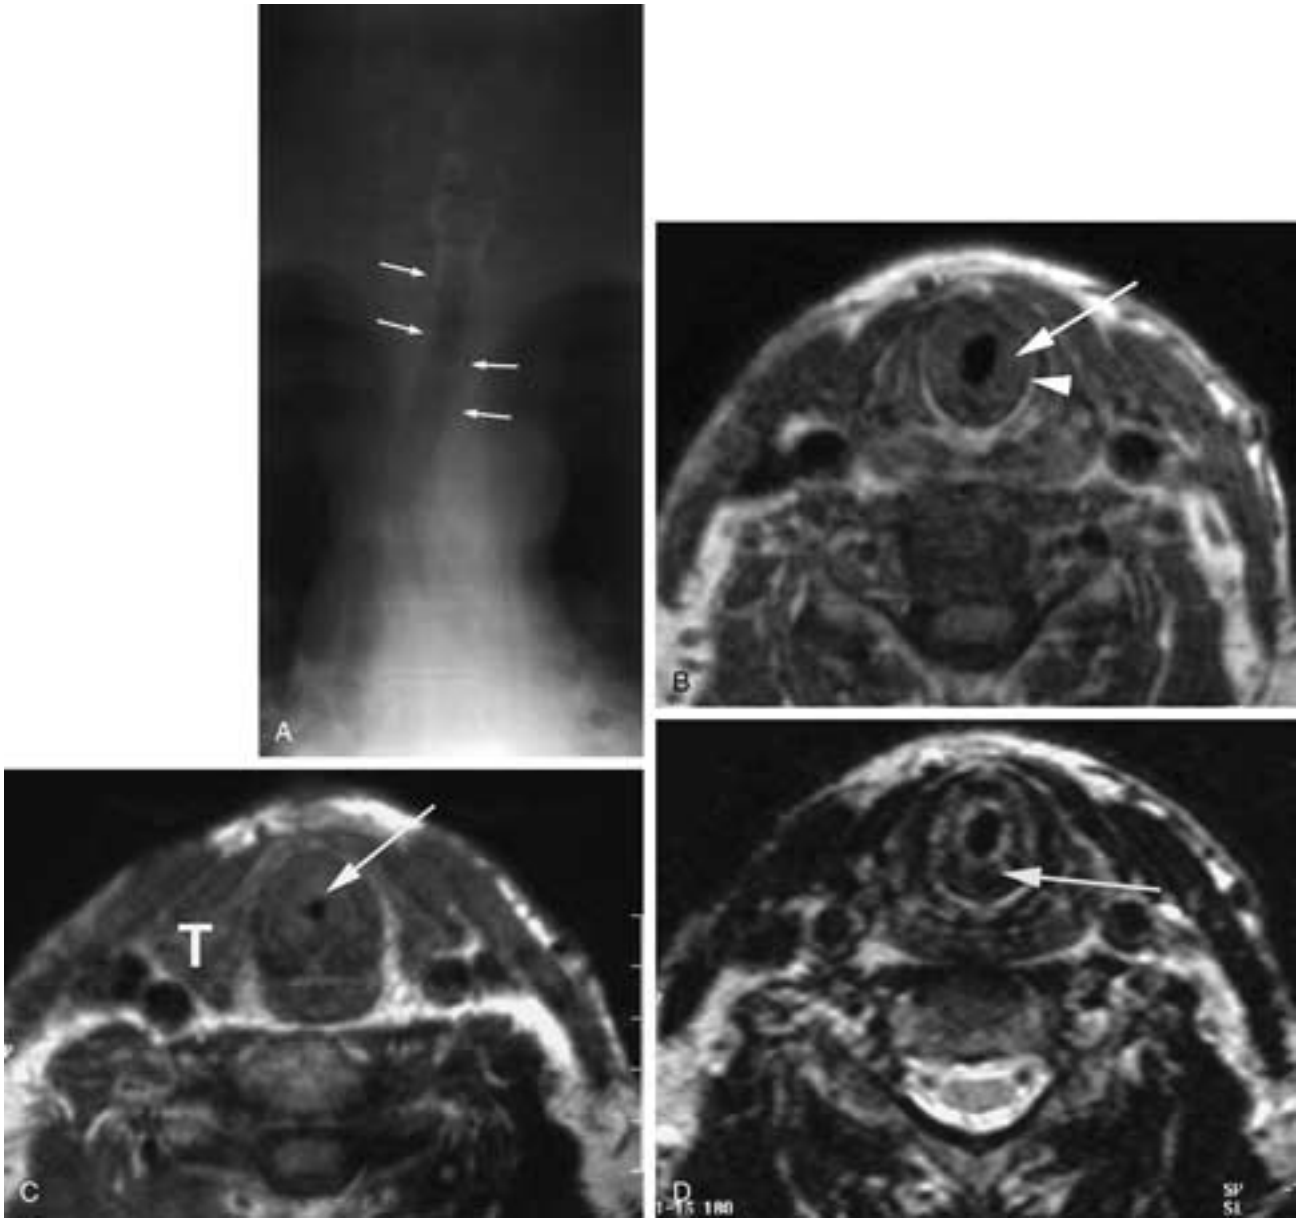

FIGURE 31-14 Amyloid. **A**, Chest radiograph of a 65-year-old man demonstrates a diffusely thickened tracheal wall on the posteroanterior view (*arrows*). **B**, T1-weighted MR image through the lower cricoid shows diffuse concentric soft tissue (*arrow*) narrowing the subglottic airway. The arrowhead indicates the position of the inner cortex of the cricoid cartilage. **C**, Axial T1-weighted image through the upper trachea shows the narrowing leaving a very narrowed airway (*arrow*). *T*, thyroid gland. **D**, T2-weighted axial image at the level of the lower cricoid shows that the abnormality has very low signal (*arrow*).

may be used to display this deformity. Another common association is marked tracheomalacia. There can be a significant decrease in the diameter of the trachea on expiration, even to the point of airway closure.

Secondary Tracheomegaly

Chronic coughing coupled with ongoing chronic inflammation has been blamed for diffuse acquired enlargement of the tracheal lumen. This has been described in cigarette smokers and in patients with cystic fibrosis.

Trauma

Tracheal trauma may result from either internal or external injury. Internal tracheal injuries are the result of inhalation of noxious fumes, gas, or steam or of aspiration. Edema, followed by rapid laryngotracheal airway obstruction, may result from chemical or thermal injury to the tracheal mucosa. Mechanical internal injuries are invariably due to iatrogenic causes, such as laryngotracheal intubation.

External traumatic tracheal injuries are more commonly due to blunt rather than penetrating trauma. The spectrum of injury includes small lacerations, tears of the posterior membranous wall, fracture of the cartilaginous rings, and complete separation. Penetrating trauma is most often the result of stab wounds or projectile injuries. Tracheal injuries most often occur in association with other severe injuries. Motor vehicle collisions are the most common cause of blunt tracheal injuries. Although rupture of the trachea in itself is a life-threatening injury, mortality is typically caused by damage to other surrounding vital organs.

Radiologic clues to tracheobronchial traumatic injury include pneumomediastinum, subcutaneous emphysema, and pneumothorax. Other signs of tracheal injury include elevation of the hyoid bone and distortion of the normal laryngotracheal air column.[53] Anteroposterior and lateral plain films of the neck are useful in identifying free air and

in evaluating for the presence of associated cervical spine trauma. Plain chest radiographs are essential in the evaluation of tension pneumothorax or hemothorax. Clinical findings include new onset of stridor, endobronchial bleeding, and respiratory failure. Direct bronchoscopy is often required for definitive diagnosis.[47]

Posttracheostomy/Postintubation Complications

The increasing use of cuffed endotracheal tubes and tracheostomy for long-term ventilation has led to characteristic injuries of the trachea. Complications from translaryngeal intubation may lead to acute airway obstruction due to postextubation glottic edema or laryngospasm. Alternatively, symptoms may develop months or even years after injury due to glottic or tracheal stenosis.[54]

A portable chest radiograph should be obtained following laryngotracheal intubation to ensure proper positioning of the endotracheal tube. Ideally, the tip of the endotracheal tube should be placed well above the carina, with the head and neck in a neutral position. It is important to recognize that flexion and extension of the neck will cause movement of the endotracheal tube of approximately 2 cm in either direction. In addition, rotation of the head can cause a 1 to 2 cm ascent of the tube. Unlike endotracheal tubes, tracheostomy tubes do not change position with head or neck movement, because tracheostomy tubes are not anchored to the nose or mouth.

Ideally, endotracheal tube lumens should be two thirds the diameter of the tracheal lumen to minimize airway resistance. Inflated tube cuffs are relatively easy to recognize on chest X-ray; their position should be checked whenever a chest X-ray is obtained. The inflated cuff should fill, but not bulge, the tracheal lumen. Rigid low-volume

cuffs have been replaced by high-volume, low-pressure cuffs, which are significantly more compliant and therefore adapt better to the variable cross-sectional shape of the tracheal lumen.[2] Most importantly, these newer cuffs provide sufficient sealing at approximately one tenth of the pressure required for rigid cuffs (about 20 to 30 mm Hg). Tracheal narrowing at the cuff site has dramatically decreased in frequency since the introduction of these high-volume, low-pressure cuffs. Immediate complications following laryngotracheal intubation can result from insertion of the tube into the right mainstem bronchus or positioning of the tube tip too close to the carina. The risk of aspiration is significantly increased if the cuff is malpositioned in the vocal cords or within the pharynx. In addition, overdistention of a malpositioned cuff may lead to vocal cord necrosis. Early complications of tracheostomy are usually associated with abnormal anterior, posterior, or lateral angulation of the tube. This can result in increased airway resistance, difficulty in clearing of secretions, or, if persistent, erosion or perforation of the tracheal wall. Anterior perforation may result in trachea-innominate artery fistula, whereas posterior perforation may lead to tracheoesophageal fistula.[55]

Late tracheostomy and postintubation stenosis can occur at the tracheostomy opening (stoma), at the balloon cuff site, or, rarely, where the tip of the tube abuts the tracheal mucosa. Most long-term complications are due to pressure necrosis at the cuff site.[44] When cuff pressure exceeds capillary pressure, the blood supply to the tracheal mucosa is compromised and ischemic necrosis results.[44] At first, the mucosa overlying the tracheal cartilages undergoes pressure necrosis. If the cuff is removed at this point, cicatricial healing usually results in an anterior tracheal web/scar. The flexible posterior wall is uninvolved. However, with greater cuff pressure, the posterior wall is also affected and a circumferential scar is produced. Usually this type of tracheal damage is limited to one or two tracheal rings at the level of the cuff-related injury (Figs. 31-17 to 31-22). Radiographically, the stenosis has a smooth edge. Typically, symptoms of stenosis develop 2 to 6 weeks postextubation and, in some patients, months or even years later.[44] Stenosis at the tracheostomy stoma may be prevented by improved

surgical technique, control of local infection, and avoidance of heavy connecting equipment.[56]

Granuloma formation at the tracheostomy site is also common. Often on CT, such a granuloma is seen as a small incidental soft-tissue mass on the anterior tracheal wall. The differential diagnosis is with dessicated secretions at the tracheostomy site.

The configuration of the trachea is often altered after tracheostomy. Interruption of the integrity of the involved tracheal cartilages often identifies the site of a prior tracheostomy (Fig. 31-23). Side-to-side collapse of the anterior tracheal configuration can also result from loss of support from the violated tracheal rings (Fig. 31-24).

Resection of the stenotic segments with anastomosis is traditionally the treatment of choice for tracheal stenosis following extubation, provided that the stenotic segment does not exceed two or three tracheal rings. Polyurethane-covered, retrievable, expandable Nitinol stents are currently under investigation as a relatively new method for the treatment of tracheal strictures (Fig. 31-25). In cases of inoperable tracheal strictures with resultant dyspnea, these

stents are suggested to be a safe and convenient nonsurgical alternative.[57]

Other less common long-term complications of intubation include tracheomalacia and ulcerative tracheoesophageal fistula. When an indwelling esophageal tube is used along with intubation, particularly in neurologically impaired patients who are ventilated for long periods of time, tracheoesophageal fistula may result. The mechanism of injury is pressure necrosis resulting from the pressure exerted by the cuff on the tracheal wall abutting a foreign body within the esophagus. This type of fistula often results in recurrent pneumonia.

Tracheal Tumors

General Considerations

Primary tumors of the trachea are rare, with malignant neoplasms representing only 2% of all upper airway tumors.[58] These tumors include primary epithelial and mesenchymal neoplasms, as well as secondary neoplasia due to either metastases or, more commonly, direct tracheal invasion from adjacent mediastinal neoplasms. In adults, primary tumors are most commonly malignant, whereas in children, benign tumors are more likely.[59]

FIGURE 31-25 Tracheal stent. A 30-year-old male who suffered from an accidental pistol discharge was intubated for 20 days. Approximately 1 week following extubation, he developed difficulty breathing and was found to have granulation tissue causing tracheal stenosis. A covered tracheal stent was placed, providing relief of symptoms. **A**, Pre-stent AP chest X-ray shows narrowing of the subglottic airway above the level of the tracheostomy (*arrow*). **B**, Anteroposterior view of the chest following stent placement demonstrates the covered tracheal stent extending from the subglottic trachea to approximately 3 mm above the carina.

Adult tracheal tumors occur between the third and fifth decades of life, with no sex predominance. Most occur at the distal third of the trachea.[58] Symptoms associated with tracheal tumors include dyspnea, cough, hemoptysis, new-onset asthma or wheezing, dysphagia, stridor, change in voice and/or hoarseness, recurrent pneumonia, and emphysema. Approximately one third of patients with tracheal tumors are initially mistakenly treated for asthmatic bronchitis.[44]

Malignant Tumors

The most common malignant tracheal tumor in adults is squamous cell carcinoma, followed by adenoid cystic carcinoma. Together, these two neoplasms account for up to 86% of all malignant adult tracheal tumors.[1] Secondary malignant tumors are due to either metastases or direct tracheal invasion by adjacent mediastinal neoplasms. The most common primary carcinomas that spread directly to the trachea are from the lung, thyroid, or esophagus (Fig. 31-26).[1] The most common carcinomas to metastasize hematogenously to the trachea are breast, gastrointestinal, melanoma, lymphoma, renal cell carcinoma, or squamous cell carcinomas of the head and neck.[60, 61]

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is the most common primary malignancy of the trachea. It typically affects middle-aged male smokers (mean age, 50 to 60 years).[2] SCC is associated with other malignant neoplasms of the respiratory and digestive tracts in one third of patients. The relatively high incidence of synchronous or metachronous tumors, found most frequently in the larynx, lung, or esophagus, makes comprehensive evaluation and follow-up imaging of the entire respiratory tract essential. Although SCC may arise at any level in the trachea, the lower trachea and the carina are the most common locations (Fig. 31-27).[58] At the time of presentation, the tumor is frequently locally advanced, with extension into the major bronchi and mediastinum.[58, 62] Malignant tracheoesophageal fistula can result from such extension. Lymph node metastases are generally seen in later disease stages, with distant metastases uncommon (Fig. 31-28). Patients may present with cough, dyspnea, hemoptysis, wheezing, stridor, and recurrent pneumonia.[2] The development of hoarseness usually indicates infiltration of the recurrent laryngeal nerve. The prognosis of patients with SCC is poor, with 5-year survival reported to be between 10% and 30%.[2]

Radiologic findings include focal and/or circumferential irregular thickening of the tracheal wall with luminal narrowing (Fig. 31-3). CT is useful in demonstrating the primary tumor, as well as extension of tumor into surrounding structures.[44]

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (ACC) is the second most common primary tracheal malignancy. Unlike SCC, there is no definite association with cigarette smoking, and the tumor occurs with equal frequency in males and females. The peak incidence of ACC is about 10 years earlier than in patients with SCC.[58] ACC arises from the tracheobronchial mucous glands and is usually located on the posterolateral wall of the trachea.[1] It is composed of small epithelial cells arranged in sheets, with fenestrations that produce a cribriform pattern. The tumor is a low-grade malignancy that tends to invade insidiously the submucosal plane of the trachea.[44] Occasionally, circumferential involvement of the trachea and bronchus without a distinct mass can be seen. ACC infiltrates through the fibrous membrane between adjacent cartilage plates and into surrounding tissues in the neck and mediastinum.[63] There may be perineural, intra-

Copyright © 2003, Mosby, Inc. All rights reserved.

neural, or pericardial great vessel involvement.[60] Indeed, perineural spread of tumor is a distinctive characteristic of ACC. ACC spreads to cervical and mediastinal lymph nodes in 10% of patients.[58] Involvement of the larynx or the recurrent laryngeal nerve may result in restriction of vocal cord motion. Hematogenous metastases spread most commonly to the lungs, with occasional spread to the brain or bony skeleton.[63]

ACC appears on radiographs as either a broad-based or pedunculated polypoid lesion. There may be smooth or nodular thickening of the tracheal wall, with associated luminal narrowing.[44] Barium swallow may demonstrate extrinsic esophageal compression or invasion. CT is useful in demonstrating the primary tumor and its extent (Fig. 31-29). However, because ACC may grow in the submucosal planes without producing a distinct mass, CT may underestimate the true extent of tumor.

The treatment of ACC involves surgical resection and anastomosis when possible. When surgical resection is performed, frozen section pathologic evaluation of the biopsy margins is recommended. Radiation therapy is used when surgery is not indicated. ACC has the best prognosis among the malignant tracheal neoplasms.[2] About 75% of patients are free of disease 5 years after therapy, but late recurrence, or survival with locally recurrent tumor for periods of 10 to 15 years, is common.[64, 65]

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is a rare tumor that can occur as either a low-grade or a high-grade malignancy. The tumor arises from the minor salivary glands lining the tracheobronchial tree and consists of mucus-secreting cells, squamous cells, and intermediate cells that have no particular differentiating characteristics.

Mucoepidermoid carcinoma has been reported in patients ranging in age from 4 to 78 years, but nearly 50% of patients are under the age of 30.[66] The most common presenting symptoms relate to airway irritation (cough or hemoptysis) or obstruction (wheezing or pneumonia).[66] In its low-grade form, mucoepidermoid carcinoma grows slowly, is noninvasive, and therefore rarely metastasizes.[67] Completely resectable low-grade tumors have an excellent prognosis, and these patients rarely have tumor recurrence. Even in its high-grade form the tumor is slow-growing and has a better prognosis than do the more common bronchogenic carcinomas. In one study,[68] only 15% of high-grade mucoepider-

FIGURE 31-26 Carcinoma of the thyroid. moid carcinomas metastasized to regional lymph nodes. The tumor may manifest as a polypoid mass in the lumen of a main, lobar, or segmental bronchus. Radiographs may demonstrate a solitary pulmonary nodule or postobstructive ''pneumonic consolidation.''[68] CT scans may reveal punctate calcification within a smoothly oval or lobulated, mildly enhancing intraluminal mass (Fig. 31-4). The incidence of intratumoral calcification—up to 14%—is much higher than that of other pulmonary carcinomas.[12]

Chondrosarcoma

Tracheal chondrosarcoma is an extremely rare neoplasm with an excellent prognosis. The tumor is typically located in the middle to distal trachea. It grows slowly, expanding both into and away from the airway. Tracheal resection is the treatment of choice.

CT demonstrates a stereotypical soft-tissue mass with coarse or stippled calcifications. The hyaline tumor matrix is characterized by high signal intensity on T2-weighted images due to its high water content and low cellularity. The stippled calcifications are not as well seen on MR imaging studies as on CT, but they may appear as areas of low signal intensity on T1- and T2-weighted sequences. The distinction between benign chondroma, a nonmalignant form of chondroid tumor, and low-grade chondrosarcoma may be impossible on the basis of imaging studies alone.[13, 69]

Benign Tumors

Benign tumors of the trachea are rare and occur most frequently in children, in whom they account for 90% of primary tracheal neoplasms.[44] Squamous cell papilloma, fibroma, and hemangioma are the most common benign childhood tracheal neoplasms.[70] Other benign tracheal tumors include granular cell myoblastoma,[71] cartilaginous tumors,[61] neurilemmoma, lipoma, fibrous histiocytoma, intratracheal goiter, benign mixed tumor, and leiomyoma.[60]

Benign tracheal tumors tend to have a smooth contour and usually are less than 2 cm in size.[60] Presenting symptoms include cough, dyspnea, wheezing, recurrent pneumonia, and hemoptysis.[2] Chest X-ray can show tracheal luminal narrowing, postobstructive atelectasis, or tumor calcification. Because of their benign nature, benign tracheal tumors are usually well-circumscribed, sometimes lobulated intraluminal tumors, with limited spread into the tracheal wall (Fig. 31-30).[60] CT with 3D multiplanar reconstructions for surgical planning can delineate the precise location and extent of the mass. Calcification is typically present in cartilaginous-based lesions, including chondromas, low-grade chondrosarcomas, chondroblastomas, and hamartomas. Lipomas are hypodense on CT scanning, whereas they have increased signal intensity on T1-weighted and intermediate signal intensity on T2-weighted MR imaging exams.[60]

T1-weighted postgadolinium MR image through the posterior fossa demonstrates a 3.5 cm diameter cystic mass with ring enhancement and internal septation. There is a slight mass effect on the fourth ventricle (left). Axial T1-weighted postgadolinium image at a more superior level (right) demonstrates an enhancing mass in the left occipital lobe (*large arrow*) with surrounding edema, as well as a small enhancing mass in the medial left temporal lobe (*small arrow*).

Benign Vascular Tumor

The most common benign pediatric large airway tumor is the hemangioma.[33] It is typically located in the subglottic portion of the larynx (i.e., subglottic hemangioma), not in the trachea. The cavernous form of hemangioma occurs more commonly than the capillary form. Neonates with airway hemangioma usually become symptomatic, with stridor and cough, within 3 months of birth.[33] Symptoms vary depending on the degree of vascular engorgement. These lesions rarely occur independently of other associated congenital vascular lesions such as hemangiomas of the skin, parotid gland, mediastinum, abdominal viscera, central nervous system, and retina. Because these lesions have a characteristic bronchoscopic appearance, biopsy is unnecessary and indeed may result in severe hemorrhage. Because many of these tumors regress spontaneously, the treatment of choice for both children and young adults is observation. For larger masses, temporary tracheostomy may be necessary for airway preservation. If the mass persists, tracheal resection may become necessary.

Hemangioendothelioma is an extremely rare lesion representing the benign counterpart of malignant hemangioendotheliosarcoma. This slow-growing tumor appears as a solid polypoid mass and contains endothelial cells surrounded by microscopic vascular channels.[72]

Squamous Cell Papilloma

The most common adult benign tracheal neoplasm is squamous cell papilloma. These tumors most often occur in middle-aged male smokers and typically involve the larynx or bronchi rather than the trachea. Squamous cell papilloma is characterized by single or multiple sessile or papillary nodular masses, with a central fibrovascular core and layers

Diffusely thickened soft tissue with nodular components encases the trachea (remaining panels).

of well-differentiated squamous epithelium (Fig. 31-31). Papillomas tend to recur after resection and may undergo malignant degeneration.

Laryngotracheobronchial papillomatosis is a condition associated with multiple papillomas. Although histologically similar to solitary papillomas, the lesions associated with this condition more often occur in young children and tend to regress spontaneously after puberty.[58] Tracheobronchial papillomatosis results from a multicentric infection by the human papilloma virus. The disease is commonly acquired at birth as the infant passes through a birth canal infected with cervical condylomata. Papillomatosis has also been noted to occur in patients with the acquired immune deficiency syndrome (AIDS).[1] Although papillomatosis is usually restricted to the larynx, in a minority of patients one or more papillomas may develop in the trachea or bronchi, which can cause airway obstruction leading to atelectasis and bronchiectasis. Papillomas rarely spread to the lung, appearing on plain chest radiographs or CT scans as multiple small, widely scattered, round pulmonary nodules, which frequently develop thin-walled cavities with air-fluid levels (Fig. 31-32).[73] Clinically, laryngeal disease presents with hoarseness, whereas tracheobronchial disease presents with wheezing, atelectasis, or recurrent pneumonia. Asymmetric tracheal or bronchial wall thickening, causing eccentric tracheal luminal narrowing, may also be present.

Cartilaginous Tumors and Hamartomas

Cartilaginous tumors of the larynx and trachea are rare and include hamartoma, chondroma, and their malignant counterpart (already discussed), chondrosarcoma. Chondromas occur with equal frequency in males and females and are most common during the fourth to sixth decades.[61] These tumors present as sharply defined masses arising from the tracheal cartilage. They vary in size from very small, causing only a slight convexity of the endotracheal surface, to very large, forming an extensive mass.[61] They are usually located in the upper trachea.[58] The mucosa overlying these regions is usually intact, and calcification may be evident on chest radiographs and CT scanning. Distinction of chondroma from low-grade chondrosarcoma is controversial even at pathologic examination. The lesions in this area tend to grow slowly, and metastasis is rare.

A hamartoma is defined pathologically as a ‘‘tumor-like malformation composed of an abnormal combination of the normal constituents of the organ in which it is found.’’[61] Most endobronchial hamartomas therefore contain masses of cartilage, fat, or cystic fluid collections, with clefts lined by bronchial epithelium. They grow slowly and are usually solitary. The average age at presentation is 45 to 50 years. These tumors can be pedunculated; consequently, one lesion can obstruct different bronchi at different times. Clinical manifestations include bronchial obstruction or

Copyright © 2003, Mosby, Inc. All rights reserved.

occasionally hemoptysis. These tumors nearly always manifest stippled calcification, although clear-cut calcification is detected on plain films in 10% to 15% of patients in most series.[74] If calcification is of the typical ''popcorn'' configuration of cartilage calcification, the diagnosis of harmatoma is virtually certain. The contrast resolution of CT scanning improves the ability to identify calcium and fat within these lesions. Surgical excision is the treatment of choice.

Carcinoid Tumor

Carcinoid tumors of the trachea characteristically infiltrate the tracheal cartilage, growing slowly in a dumbbell configuration. The age range at presentation is variable, but the peak incidence is in the fifth to sixth decades. The atypical form of bronchial carcinoid has cellular and clinical features intermediate between those of typical carcinoid and SCC.[75] All types of carcinoid tumors are of neuroendocrine origin and are thought to form a spectrum of varying degrees of malignancy. Because these tumors are vascular, hemoptysis is a common presenting complaint. Other presenting symptoms include cough, pneumonia, atelectasis, and wheezing. The tumor may be predominantly intraluminal, assuming a polypoid configuration, or predominantly extraluminal (an ''iceberg'' lesion). Calcification and/or ossification within the tumor may occur.[76] Cushing's syndrome may develop due to secretion of corticotropins by tumor cells, and carcinoid *syndrome* uncommonly occurs as a complication of carcinoid tumor.[77] CT scanning provides superb anatomic localization of both the intraluminal and extraluminal components of the tumor. CT also may identify calcification and enhancement within the tumor.

Recurrence of carcinoid tumor is a significant problem, particularly after surgical resection of pedunculated tumors. Other methods of treatment, such as fulguration, cryotherapy, and laser ablation, seem to reduce recurrence rates more than local bronchoscopic resection.

Benign Mixed Cell Tumors

Benign mixed cell tumors (pleomorphic adenomas) of the trachea are histologically similar to benign mixed tumors of the major salivary glands. These contain a mixture of epithelial cells, cartilaginous elements, and mesenchymal cells. Although these lesions are less commonly found in tracheal or bronchial minor salivary glands than in major salivary glands, they constitute the fifth most common type of benign tracheal mass. Treatment consists of complete excision; recurrence is unusual.

Tumor-Like Conditions

Many nonneoplastic diseases can present as tracheal or bronchial masses. Infectious diseases such as tuberculosis, systemic histoplasmosis, or even coccidioidomycosis can form intraluminal granulomas that may simulate primary tumors. Traumatic injury of the trachea can also incite granuloma formation. Occasionally, aspirated foreign bodies may adhere to the tracheal wall and simulate tumor. Cysts and mucoceles in children must be differentiated from common tumors such as hemangiomas and fibromas.

Ectopic thyroid tissue in the trachea, although rare, can simulate neoplastic disease. Ectopic thyroid tissue is found in 1 of 7000 to 18,000 patients who undergo thyroid gland surgery (with a female predominance). It may come to clinical attention due to growth of normal thyroid tissue,

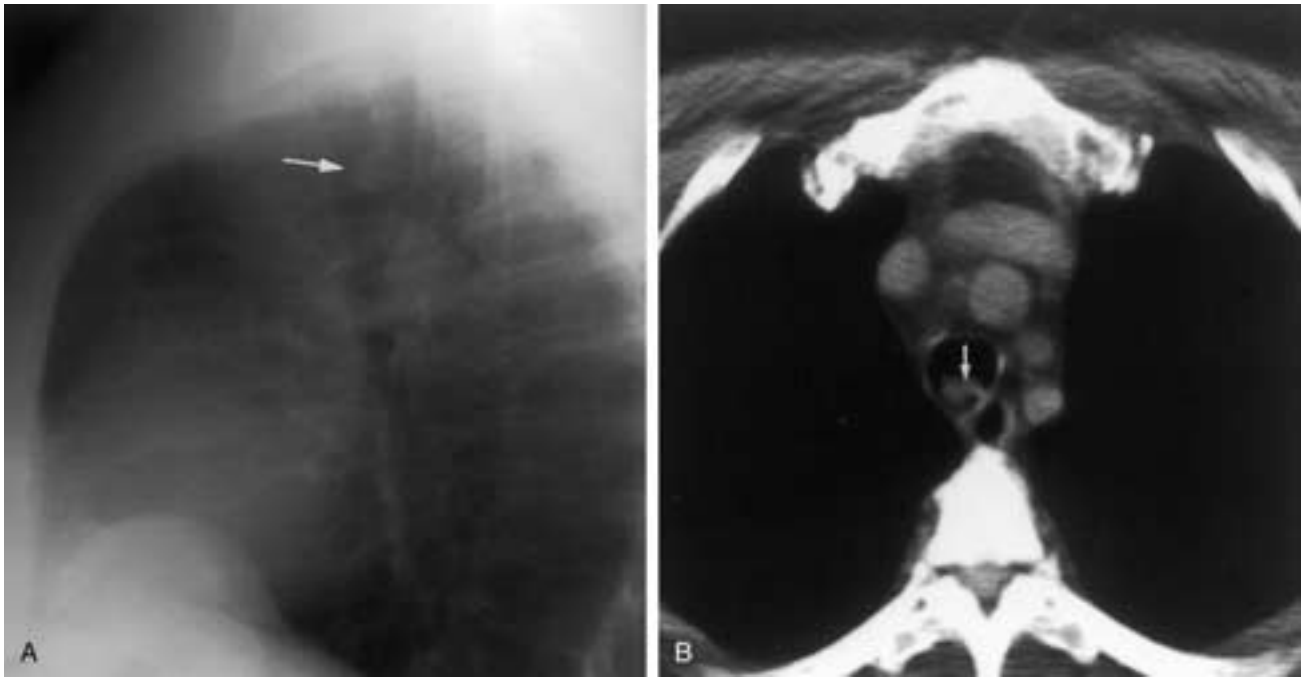

FIGURE 31-31 Squamous papilloma. Lateral chest radiograph (**A**) and noncontrast axial chest CT (**B**) demonstrate a polypoid endoluminal mass (**B**, *short arrow*, **A**, *long arrow*) protruding from the posterior left lateral wall of the midtrachea just above the level of the aortic arch.

goitrous enlargement, or malignant degeneration (Fig. 31-33). A characteristic location is 2 to 3 cm below the vocal cords, although it may present more distally in the trachea. Frequently, intratracheal goiter is associated with goitrous enlargement of the normally positioned thyroid gland (Fig. 31-34). Intratracheal thyroid tissue may manifest years after thyroidectomy because of compensatory hyperplasia. Surgical resection is recommended, as malignant degeneration occurs in 10% of cases.

- Evaluation of Therapeutic Strategies

OVERVIEW OF A NORMAL VFSS
CONCLUSION

INTRODUCTION

The process of transferring food or liquids from the oral cavity to the esophagus consists of a series of intricately connected and exquisitely timed biomechanical events. When abnormalities of oropharyngeal swallowing occur, they can lead to potentially life-threatening health outcomes such as aspiration pneumonia, dehydration, and/or malnutrition, not to mention the devastating social consequences of the problem. While epidemiologic data are sparse, current estimates on the incidence and prevalence of dysphagia indicate that 16% to 22% of adults over 50 years of age experience swallowing difficulties; 12% to 13% of acute care hospitalized patients and about 60% of residents in long-term care facilities have dysphagia.[1]

Stroke is the leading cause of oropharyngeal dysphagia. Approximately 30% to 90% of patients with acute stroke have signs of dysphagia, and of those, 38% to 50% have aspiration on the videofluoroscopic swallowing study (VFSS).[2–4] Other progressive neurologic disorders such as amyotrophic lateral sclerosis, dementia, and Parkinson's disease also affect swallowing function. Moreover, oropharyngeal swallowing disorders can be manifestations of any of a multitude of systemic diseases such as those illustrated in Table 32-1.[1]

Oropharyngeal dysphagia is usually the result of a physiologic disorder of the swallowing process rather than a

mucosal or structural aberration. Therefore, diagnosis demands an understanding of the complexity of the multifaceted temporal, spatial, and pressure-related components of the swallowing process. While several instrumental diagnostic procedures are available for diagnosing oropharyngeal swallowing disorders, such as endoscopy, scintigraphy, and ultrasonography, each provides only limited information. The dynamic VFSS provides the most complete appreciation of the individual elements of the oral, pharyngeal, and laryngeal events that drive the bolus through the oral cavity into the cervical esophagus. Its comprehensiveness has earned it the status of the gold standard.[5, 6]

VFSS provides immediate information on bolus transit in relation to structural movements of the oral cavity and hypopharynx. The purpose of the examination is not simply to determine whether the patient is aspirating. The study is important because it helps define the underlying physiology of the swallowing disorder for rehabilitation planning. By careful analysis of the sequence of events during oropharyngeal swallowing, therapeutic strategies can be introduced systematically and their effectiveness evaluated. A critical objective is to determine a prescription for safe and effective feeding and swallowing.[7, 8]

Unlike the barium swallow, which has been the mainstay of fluoroscopic imaging of the upper aerodigestive tract for about 50 years, the VFSS is a relatively new examination in the armamentarium of speech language pathologists for examination of oropharyngeal swallowing. The VFSS is widely used in hospital and rehabilitation settings and has recently been adapted for mobile use with a C-arm fluoroscope in long-term care and school facilities. The study is alternatively known as a *cine-swallow study* after the cinefluorographic technology that preceded video recordings of dynamic radiographic events. It has also been called the *cookie swallow*, a term coined by Logemann[9] to emphasize the assessment of the oral stages of swallowing using cookies and barium as the contrast medium. The term most widely used today is *modified barium swallow*, which is frequently confused with *barium swallow*. Others have referred to the study as the *oropharyngeal motility swallowing study*,[10] *dynamic swallow study*,[11] and *videofluoroscopic oropharyngeal swallowing study*.[12, 13] For the purposes of this chapter, the term *videofluoroscopic swallowing study* (VFSS) will be used.

The VFSS has high clinical utility. In a recent study by Martin-Harris et al.,[7] 83% of their 608 consecutive heterogeneous subjects displayed abnormal swallowing on VFSS and 48.4% of those patients benefited from compensatory swallowing strategies that improved their swallowing safety and efficiency. However, the clinical utility of the examination depends on comprehensive evaluation of muscular movements in relation to bolus flow, not simply on evaluation of the bolus flow itself. Focus on the bolus flow alone, which is common among novice clinicians, provides information about symptomatology but not etiology. Successful therapeutic compensations or maneuvers are based on an understanding of the etiology of the disorder.

MULTIDISCIPLINARY NATURE OF THE VFSS

Optimally, the radiologist in collaboration with a speech pathologist trained in dysphagia evaluation and management perform the VFSS together, with each professional bringing his or her individual expertise. The radiologist is trained to identify structural abnormalities and disease processes, while the speech language pathologist possesses an in-depth understanding of the dynamics of oral and pharyngeal movements during normal and disordered swallowing and is familiar with the therapeutic strategies that can improve swallowing safety and efficiency. The speech language

Copyright © 2003, Mosby, Inc. All rights reserved.

pathologists should be acutely aware of his or her diagnostic range and should rely heavily on the radiologist for identification of disease. The radiologist provides input about radiation safety procedures and positions the fluoroscope to provide the clearest image of the area under consideration.[14] Together, both professionals estimate the risk of continuing to administer contrast to the patient and make recommendations for oral intake based on the results of the study.

THE DIFFERENCE BETWEEN THE VFSS AND THE BARIUM SWALLOW

The traditional barium swallow study differs from the VFSS in several ways. The routine procedure for the barium swallow includes a full-column, single-contrast or mucosal relief *double-contrast study* and a motility assessment of the esophagus.[15] The fluoroscopy unit is focused on the hypopharynx and follows the bolus as it traverses the esophagus into the stomach. The focus of this study is on the thoracic esophagus, and the oral manipulation of the bolus is not primarily evaluated. Aspiration is noted if it occurs, but the mechanism of aspiration cannot be determined unless the oral and pharyngeal stages of swallowing are carefully examined. Gas-producing granules and high-density barium may be administered for assessment of possible mucosal irregularities, and high-density liquid barium is used to assess esophageal motility. If a stricture or esophageal narrowing is suspected, a 13 mm barium tablet may be given. In the barium swallow, the patient is examined in upright and recumbent positions and in anterior-posterior (AP), lateral, and oblique projections. Usually single or sequential plane films taken during the swallow are generally adequate to capture the bolus as it moves through the esophagus.[15]

By comparison, the VFSS focuses on the oral cavity, oropharynx, nasopharynx, hypopharynx, larynx, and cervical esophagus. In an attempt to simulate the habitual swallowing function, patients are required to swallow controlled and uncontrolled volumes of barium contrast with a variety of consistencies while seated upright and imaged in the lateral and AP projections. Typically, esophageal function is not examined in detail during the VFSS. However, a survey scanning the esophagus to determine whether the contrast material has passed through the gastroesophageal junction provides some screening information about esophageal function and may suggest that further evaluation is needed. This is especially important since 35% of patients have combined pharyngeal and esophageal components to their dysphagia and the site of the lesion does not correspond accurately with the patient's complaint.[16]

INDICATIONS FOR THE VFSS

Patients who present with signs of pharyngeal dysphagia on xclinical examination are most appropriate for a VFSS study. Problems may include overt complaints of coughing and choking when eating or drinking as well as signs of food or liquid becoming ''caught in the throat.'' While aspiration may be obvious, it may also present silently in the form of a weak volitional cough or a wet or ''gurgly'' vocal quality after eating or drinking. Symptoms of silent aspiration are strongly related to transglottic aspiration on videofluoroscopic evaluation.[2] Splaingard et al.[17] observed that 40% of their subjects who aspirated on VFSS were not identified as having aspirated on the bedside examination.

Patients should be alert and be able to accept food by mouth in a reasonable length of time. If therapeutic strategies are to be evaluated, patient cooperation is necessary. Hemodynamically unstable patients or those with severe deconditioning who have not had practice sitting upright should be transported to the radiology suite only with extreme caution, as the effect of positioning the patient may overwhelm and fatigue the patient, affecting the outcome of the examination. In such cases, it may be prudent to defer the examination until the patient's health improves. Patients should be able to sit upright or close to upright comfortably for the procedure for several minutes.

CLINICAL EXAMINATION

In most instances, the patient is known to the speech language pathologist prior to the VFSS. Previous clinical encounters permit the clinician to obtain a comprehensive medical and swallowing history and to perform an assessment of oral motor and sensory function. In addition, it is likely that the speech language pathologist has observed the patient swallowing liquids and solids. The clinical swallowing evaluation allows the clinician to hypothesize about the nature of the underlying pathophysiology of the swallow and to attempt therapeutic strategies at the bedside. In addition, the patient may be taught compensatory swallowing strategies in preparation for the VFSS.

In certain settings, however, the VFSS may be the first encounter, and thus a detailed history is required to plan the study. Relevant history information details the onset and progression of the patient's dysphagia symptomatology as well as current diet, food consistency preferences and avoidances, duration of mealtimes, strategies the patient has found helpful to alleviate the problem, unintended weight loss, and medical consequences of the dysphagia. If the patient is fed nonorally via a gastrostomy or nasogastric tube, the circumstances surrounding its placement must be understood. The patient's medical and surgical history and current medications are examined for their etiologic contribution to the dysphagia, including recent hospitalizations for pneumonia, radiation therapy to the head and neck, and/or gradual changes in speech intelligibility.

Prior to the radiographic examination, an assessment of the motor and sensory function of the oral mechanism is performed. Note is made of asymmetries of labial, lingual, and palatal movements, reduction in range of motion, strength or coordination, and restricted sensation to light touch. An absent gag reflex is noted, as well as impairment of volitional coughing and laryngeal excursion during dry swallowing.

PROCEDURE FOR THE VFSS

The VFSS aims to simulate habitual swallowing behavior as much as possible, taking into account that barium contrast does not closely resemble typical solid or liquid substances. Although several standard protocols have been described,[6, 18, 19] there is no real consensus about the most appropriate protocol, probably because no one protocol is suitable for all patients. The VFSS is tailored to the patient's complaints, medical profile, cognitive status, results of the clinical swallowing evaluation, and the patient's risk of aspiration. In all instances, efforts are made to limit aspiration of the contrast material. In some cases, the study is terminated when the patient aspirates. However, in most instances, controlled volumes of different barium consistencies coupled with swallowing maneuvers allow for evaluation of their effectiveness. The general sequence of the procedure is illustrated in Table 32-2 and is adapted from Mills.[20]

Positioning

The patient is seated upright in a comfortable posture in a chair. Chairs designed specifically for the VFSS are available. These chairs fit into the fluoroscopic unit and permit easy transfer of patients from stretchers or wheelchairs, as well as easy position changes from lateral to AP views. The VFSS always commences with the patient in the lateral view. The field of view includes the lips anteriorly, the posterior pharyngeal wall and cervical spine posteriorly, the nasopharynx superiorly, and the upper esophageal segment and C7 inferiorly (Fig. 32-1A). This wide view enables assessment of the various stages of swallowing at one time. After contrast with the various consistencies is administered and any necessary maneuvers are performed, the patient is turned to the AP projection for observation of the symmetry of muscular contraction. For the AP views, the fluoroscopic unit is focused on the oral cavity so that the palate forms the superior border of the image and the vocal folds and tracheal column form the inferior border. To improve the quality of the image, the field is collimated so that the lateral borders of the mandible are at the outer aspect of the field of view (Fig. 32-1B).

Contrast Agents

Patients are given small amounts of barium sulfate in various forms such as liquid, paste mixed with pudding or applesauce to create a semisolid consistency, and a portion of a cookie coated with barium paste. Since the study is not designed to identify mucosal pathology, it is not necessary to use a contrast agent with a very high weight/volume concentration. Some clinicians attempt to replicate the

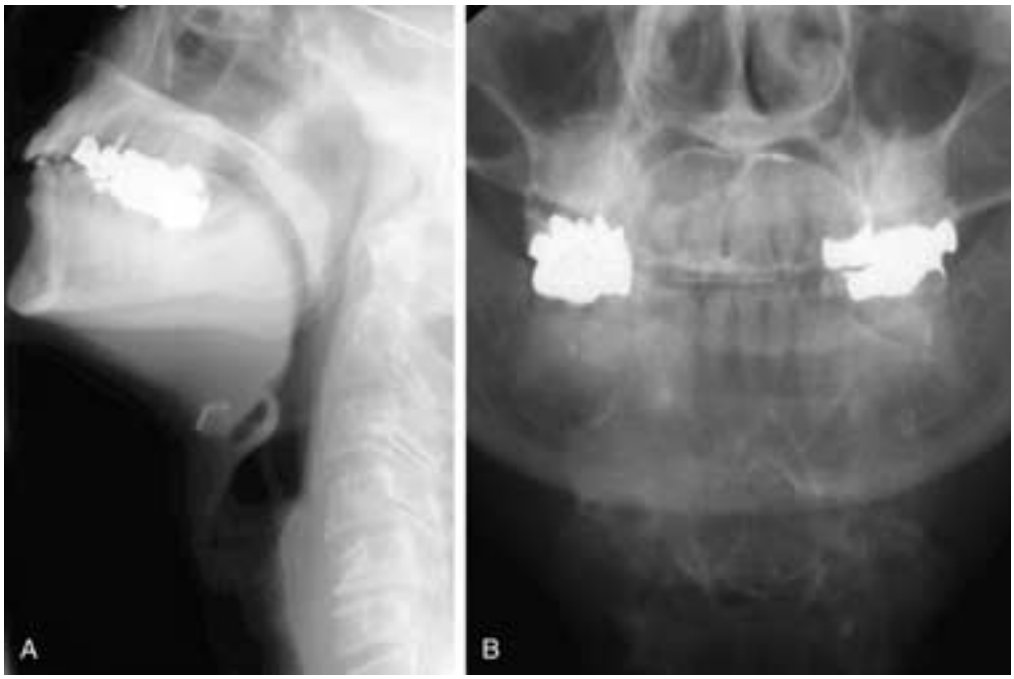

FIGURE 32-1 Ideal view for imaging oropharyngeal swallowing in the (**A**) lateral and (**B**) AP projections.

thinnest liquids, such as water or juice, by diluting the barium liquid. While this more closely resembles the viscosity of thin liquids, its reduced radiodensity reduces the reliability with which small amounts of aspiration can be accurately detected.

The boluses are measured and are given in increments to determine performance with a variety of volumes. Contrary to expectation, some patients have greater difficulty initiating a swallow with smaller liquid boluses than with larger ones. Sometimes it is necessary to evaluate the patient while swallowing thickened liquids or specially prepared foodstuffs such as bread and hard meats coated with barium. In some settings, patients are encouraged to bring foods with which they have difficulty, the goal being to simulate the scenario that causes the dysphagia. If the patient has difficulty taking pills, a 13 mm barium tablet may be given, although extreme caution should be exercised if the patient is seen to experience moderate to severe oropharyngeal dysphagia. Aspiration of a barium tablet can lead to significant complications, particularly in a compromised patient.

Recording

Fluoroscopic images are recorded in real time by high-definition video recording equipment for later analysis and review. Image data can be stored on videotape or, with new technology, in digital form on a hard drive or digital video disk. Because of the complexity of the events of the swallow occurring in a short period of time, video recorders should be capable of slow-motion review and frame-by-frame analysis. A microphone is needed to record the instructions to the patient and to record audible responses such as coughing and the patient's vocal quality. Static or spot films can be taken during the fluoroscopic procedure if suspected pathology is identified.

In an effort to reduce radiation exposure, some clinicians use pulse fluoroscopy, particularly during mastication of solid boluses. Since swallow onset after mastication is variable, it is possible to miss the important biomechanical events if the fluoroscope is turned off. Rapid-sequence digital radiography has become available in many hospitals. Among the advantages of this system are the excellent image resolution quality (1024 lines per inch), the relatively low-dose radiation, and the ability to enhance the image on a frame-by-frame basis.[20] However, one disadvantage is that its capture rate of six frames per second may be too slow to ensure visualization of the intricacies of the pharyngeal swallow, which in normal instances can be completed in less than 1 second.

While clinicians should be mindful of the cumulative recording time, the examination should be long enough to obtain the answers to the critical questions. Fluoroscopy time can be controlled by thorough preparation for the examination based on the history and the findings of the clinical swallowing assessment. Clinicians should take care to administer only that contrast necessary to answer particular questions reliably, expecting to extrapolate some information to slightly larger boluses or to consistencies that differ minimally in viscosity. For the beginning clinician, it may be necessary to review the video recording partway through the study before proceeding with the remainder of the examination.

Traditionally, the radiologist terminates the barium swallow examination when aspiration is detected. However, sometimes aspiration is observed early in the examination and terminating the study will not allow evaluation of the efficacy of therapeutic strategies that may indeed eliminate aspiration. Compensatory or rehabilitative maneuvers are introduced if the patient aspirates or demonstrates inefficient swallowing behaviors. Such maneuvers are assessed for their effectiveness in both the lateral and AP projections. Ideally, more than one trial per bolus is needed to improve the reliability of the findings.

Termination of the study will depend on patient-specific parameters such as the amount of aspiration, the patient's sensitivity to the aspiration, effectiveness of clearance from the trachea, and the underlying medical history. For example, an ambulatory patient, who has no history of aspiration pneumonia, is cognitively intact, and whose airway is effectively cleared with a cough is more likely to tolerate aspiration than a patient who is bed bound and has recently been mechanically ventilated, with a weak cough.

Reporting the Findings

In many facilities, the speech pathologist and radiologist generate separate reports on the results of the VFSS. Ideally, a report that details observations of the structural components of the oropharyngeal mechanism, as well as a description of the biomechanical events of the swallow and the results of therapeutic procedures, would reflect the collaborative nature of this radiographic procedure.

NORMAL SWALLOWING

Traditionally, the description of swallowing is divided into four stages: the oral preparatory stage, the stage of oral transit, the pharyngeal stage of swallowing, and the esophageal stage. This description is artificial in that it fails to capture the fluidity of the normal swallow and it ignores the impact one stage has on the progress of the next. In this section, an attempt is made to outline the features of the normal oropharyngeal swallow from a physiologic standpoint using the pressure generation model as the basis for the discussion. In the section on Interpretation of Findings, the radiologic manifestations of the normal and abnormal physiology of swallowing are discussed. However, in order to make clinical sense of radiographic findings, it is necessary to understand the complexity and fluidity of normal swallowing physiology.

The process of safe and efficient swallowing demands exquisite timing and coordination of more than 30 pairs of muscles and 6 cranial nerves that are under voluntary and involuntary nervous control. Boluses are prepared and propelled through the oral cavity, pharynx, and esophagus and enter the stomach in an extremely complex process that lasts for less than 20 seconds, with the longest phase occurring in the esophagus. A dynamic pressure gradient, generated by the opening and closing of a series of ''valves''

Copyright © 2003, Mosby, Inc. All rights reserved.

in the tube-like structure of the oral cavity and hypopharynx, is responsible for propagation of the bolus into the esophagus.

Oral Preparatory Stage

In the first preparatory stage, the food or liquid is manipulated until it is ready for swallowing. This stage involves mastication of solid boluses and positioning of semisolid or liquid boluses for transfer into the hypopharynx. Bolus preparation is under voluntary control and can be halted at any point. It is during this stage that pleasure is taken from the food by stimulation of the multiple chemoreceptors and sensory receptors located on the tongue dorsum and to a lesser degree in the pharynx. The length of this stage varies, depending on the consistency of the material being manipulated, the presence of saliva, the individual preference of bolus size for swallowing, and the style of chewing. Liquids, including saliva, and semisolid materials such as pudding require minimal manipulation. The bolus is formed by pressure generated by contraction of the buccinator and labial musculature, and elevation of the edges of the tongue aids in shaping the bolus and positioning it on the tongue dorsum in preparation for propulsion of the bolus to the pharynx. Simultaneously, the soft palate is depressed against the tongue base, creating a palatoglossal seal, which prevents leakage of liquids or semisolids into the pharynx before they are ready to be swallowed.

During mastication of solid foods, finely coordinated movements of intrinsic and extrinsic lingual muscles move the bolus to the dental arches. Opening of the jaw and lateral and rotary movements of the mandible against the maxilla grind food into smaller pieces. Cohesive bolus formation of solids and liquids depends on the presence of sufficient saliva that binds the material together, tongue movement that sweeps the crevices of the oral cavity, and lip closure that prevents spillage of food from the mouth. It is important to note that during mastication, unlike manipulation of liquids and semisolids, the bolus is not completely contained in the oral cavity. Here the rotary and lateral mandibular movements release the palatoglossal seal, and some material falls into the valleculae prior to the onset of the pharyngeal phase.

Oral Transport Stage

During the second stage of swallowing, the oral transit or oral transport phase, the prepared bolus is propelled into the pharynx by a series of anterior-to-posterior wave-like contractions of the tongue in contact with the incisors and the lateral borders of the palate. The soft palate elevates, permitting the bolus to enter the pharynx and preventing nasal regurgitation. Simultaneously, the floor of mouth muscle complex, including the suprahyoid muscles, contracts and the base of the tongue depresses and moves anteriorly, forming a chute down which the bolus can flow. This, in turn, causes pressure on the bolus and drives it cleanly into the pharynx. This stage of swallowing, illustrated in Figure 32-2, lasts for less than 1 second and is under voluntary neural control.

Pharyngeal Stage

The events of the pharyngeal stage of swallowing occur concomitantly with the oral transport stage and can be described as a single pressure-driven event in which the oral cavity, pharynx, and cervical esophagus form a single tube. The ‘‘valves’’ of the system (lip closure, contraction of the buccinators, closure of the velopharyngeal port, adduction of the vocal folds, and contraction of the pharyngeal musculature) act to close the cavity and, in conjunction with the ‘‘piston-like movement’’[21] of the tongue and contraction of the pharyngeal constrictor muscles, generate pressure within this continuous tube. A pressure differential occurs as the hyolaryngeal complex elevates superiorly and anteriorly, opening the upper esophageal segment and propelling the bolus into the cervical esophagus.[22]

The pharyngeal stage is the most complex stage of the swallow in terms of muscular coordination and timing. It is during this stage that airway protection must occur simultaneously with opening of the upper esophagus to prevent aspiration into the trachea and to facilitate transfer of the bolus into the esophagus.

Stimulation of the sensory impulses of cranial nerves IX, X, and XI (glossopharyngeal, vagus, and accessory, respectively) marks the onset of the pharyngeal stage of swallowing. The glossopharyngeal nerve transmits visceral sensation from the pharynx, taste sensation from the posterior one third of the tongue, and touch, pain, and thermal sensation from the mucous membranes of the oropharynx and posterior tongue.[23] The superior laryngeal branch of the vagus nerve supplies sensation to the mucosa covering the epiglottis and the posterior tongue and endolarynx, while the recurrent laryngeal nerve supplies sensation to the subglottis and the mucosa of the cervical esophagus.[24] These sensory impulses travel to the nucleus tractus solitarius (NTS) in the medullary reticular formation located within the brainstem, which integrates multiple functions related among others to respiration and swallowing[24] (p. 70). Neurons from the NTS project to other brainstem regions including the nucleus ambiguus (NA). The motor neurons of the NA innervate the palatal, pharyngeal, laryngeal, and esophageal muscles critical to the pharyngeal stage of swallowing. Together with input from higher cortical and subcortical structures, the coordinated and precisely timed actions occurring in the pharyngeal stages of swallowing are possible.

Airway protection, opening of the upper esophagus, and pharyngeal clearance transform the aerodigestive tract from its function as a respiratory system to a deglutitional system. Airway protection takes place in the horizontal and vertical planes, begins simultaneously with bolus entry into the pharynx, and can occur even when the bolus is first placed in the mouth.[25] Intrinsic laryngeal closure begins with adduction of the vocal folds (contraction of the thyroarytenoid, vocalis, interarytenoid, and lateral cricoarytenoid muscles) toward the midline.[26, 27] The vestibular vocal folds and the supraglottis also adduct to close the laryngeal airway. Vocal fold adduction is the first event to occur during the swallow and continues throughout the swallow sequence. Shaker et al.[27] noted that in one third of their normal subjects, true vocal fold approximation was incomplete prior to laryngeal elevation and during the pharyngeal swallow. This may

account for the frequently observed phenomenon in normal adults of trace and transient liquid penetration high in the laryngeal vestibule, which is extruded out as the swallow progresses.[28]

The upright suprahyoid portion of the epiglottis forms the posterior border of the vallecula at the base of the tongue, and acts to divide the advancing bolus and direct it down the lateral channels of the hypopharynx (pyriform sinuses) and into the cervical esophagus. As the pharyngeal stage of the swallow progresses the epiglottis inverts, contributing to the closure of the laryngeal inlet. The epiglottis moves passively, and its inversion is dependent on the contraction of its muscular attachments in a two-stage process. Contraction of the suprahyoid muscles pulls the hyolaryngeal complex anteriorly, and with it the epiglottis to the horizontal plane. Thereafter, contraction of the thyroepiglottic muscle inverts the epiglottis to a completely downfolded position assisted by pressure from the bolus above.[29–31] Of note, epiglottic downfolding may be inconsistent in occurrence. Ekberg and Nylander[32] noted that the epiglottis can remain upright in normal adults when a small bolus is swallowed. Appreciation of the passive nature of epiglottic movement per se is important in interpreting abnormal deflection on a radiographic examination because the function of the surrounding structures must be examined.

Respiration ceases for approximately 0.75 second during an obligatory apneic period. This period of apnea varies with bolus consistency and volume; the larger the bolus volume and/or the more viscous its consistency, the longer the duration of apnea.[25] Respiration resumes after the swallow on the expiratory phase of the respiratory cycle, which is thought to have a role in clearing material possibly penetrating the laryngeal vestibule.

Opening of the cervical esophagus occurs as the suprahyoid muscles contract, pulling the larynx upward, forward, and away from the posterior pharyngeal wall. Conventional wisdom suggests that opening of the upper esophagus is achieved through relaxation of the tonically contracted cricopharyngeus muscle. While intrinsic relaxation of the pharyngoesophageal segment must occur, research has shown that the movement of the entire larynx upward and forward approximately 2 to 2.5 cm under the tongue base affects the major opening force, assisted by intrinsic relaxation of the pharyngoesophageal segment and by the bolus pressure from above.[33, 34] Opening of the upper esophageal segment is modulated by bolus variables such that larger or more viscous boluses result in earlier onset, greater magnitude, and longer duration of opening than smaller, less viscous boluses.[25, 34]

Contraction of the obliquely arranged pharyngeal constrictor muscles generates additional pressures on the tail of the bolus, especially at the area between the valleculae and the arytenoid cartilages. These sequential contractions contact the tongue base, acting as a clearing force to remove boluses from the pharyngeal recesses and propel them into the cervical esophagus.[35] Pharyngeal bolus transit is very rapid, occurring in less than 1 second, and is consistent in duration regardless of the viscosity or volume of the bolus or the age of the patient.

Esophageal Stage

In contrast to the oral and pharyngeal stages of swallowing, the esophageal stage is the longest, lasting for 8 to 20 seconds in normal adults. The transfer of food from the mouth to the stomach via the esophagus results from the coordinated relaxation of the upper and lower esophageal sphincters and the peristaltic contraction waves that sweep the length of the conduit after the pharyngeal swallow. Primary and secondary peristaltic waves are the result of contraction of the striated and smooth esophageal regions, which shortens the esophagus in rostrocaudal sequences. The mass of the bolus entering the esophagus initiates primary and secondary esophageal contractions. If the cricopharyngeus does not close in an appropriately rapid manner, esophagopharyngeal reflux can occur. Thus, the timing of both the opening and closing of the cricopharyngeus is critical to a normal swallow. In addition, this region must remain open long enough to allow the entire bolus to enter the esophagus. These factors illustrate the delicate and precise timing of events during a normal swallow, and they are discussed later in the chapter.

EFFECTS OF AGING ON OROPHARYNGEAL SWALLOWING

The features of normal swallowing described above undergo changes with aging, even in the elderly normal. These changes must be recognized when evaluating the swallowing of older patients in order to avoid overdiagnosis and overtreatment of normally occurring phenomena. There is a natural progressive change in the sensory and motor components of oropharyngeal swallowing that may make older normal persons vulnerable to dysphagia. Physiologic features of swallowing in older individuals include slower manipulation of solids and a delay in initiating the pharyngeal stage of swallowing, which results in an unprotected airway for an increased length of time. The range of opening of the upper esophageal segment is reduced as a result of tissue fibrosis and degeneration, which in turn results in more pharyngeal retention than in a younger patient. High laryngeal penetration of the laryngeal vestibule may be observed in older individuals before completion of the swallow. However, persistent laryngeal penetration and aspiration is never normal, and the material is usually ejected from the laryngeal inlet as the swallow progresses. Aging can bring with it loss of skeletal muscle mass, as well as changes in muscle strength and muscle contraction, all of which may contribute to a weaker bolus drive and increased stasis in the oral cavity and pharynx. Furthermore, aging individuals are more susceptible to disease, which in turn restricts the functional reserve capacity in dealing with the normal structural and physiologic changes that accompany normal aging.

In elderly patients, dysphagia is frequently the result of combinations of several conditions such as diabetes, chronic obstructive pulmonary disease, congestive heart failure,

Copyright © 2003, Mosby, Inc. All rights reserved.

renal failure, immunocompromised status, and/or cachexia. Some conditions that are not sufficient to cause dysphagia in younger adults can challenge the naturally declining physiology of older adults. Such conditions include the presence of a nasogastric feeding tube, medication side effects, and chronic illness.[36–38]

INTERPRETATION OF FINDINGS

Interpretation of the dynamic images of the VFSS must accomplish two goals. The first is to identify the presence of an oropharyngeal swallowing disorder and to describe the physiologic underpinnings of its component parts. The second but equally important goal is to determine which therapeutic maneuvers are likely to facilitate improved swallowing safety and efficiency. A declaration of the presence or absence of aspiration or bolus obstruction or hesitation is insufficient. In order to exploit the therapeutic value of the VFSS, it is necessary to consider the reason for symptoms of aspiration or residue. Logemann,[12] a pioneer of the VFSS, takes a very strong position on this point: ''Aspiration and residue are symptoms of swallowing disorders, not swallowing disorders themselves . . . the anatomic and/or neurologic muscular dysfunctions are the actual disorders leading to the symptom for which the treatment is designed'' (p. 71). In contrast, an exhaustive interpretation of any of the many components of the swallow may not yield useful clinical information and may be too time-consuming. Clinicians should resist the urge to comment exclusively on bolus location in the oral cavity, pharynx, airway, or cervical esophagus and should consider the aberrant forces that caused the bolus to flow in the observed directions.

Therefore, the challenge is to develop a schema that permits identification of the salient abnormal events in order to arrive at an integrated understanding of the biomechanical basis of impairment. These data form a foundation for assessing therapeutic maneuvers. Assessment of the videofluoroscopic images involves description of abnormal anatomy, analysis of the timing and coordination of the biomechanical events of the swallow, and determination of laryngeal penetration. Finally, the effectiveness of swallowing strategies attempted during the VFSS is evaluated in order to make recommendations for oral nutrition. This schema, outlined in Table 32-3, follows the outline suggested by Murray.[39]

Dodds et al.[22] make the important point that the goal of interpretation is not to diagnose disease. There are very few typical presentations of diseases on the VFSS, and symptoms of a variety of diseases or conditions can appear similarly on the study. For example, a severely deconditioned patient with significant loss of muscle mass and pharyngeal weakness may closely resemble a patient with polymyositis with respect to solid bolus swallowing. Thus, it would not be possible to offer a differential diagnosis of polymyositis when viewing the results of a VFSS alone. The clinical history is very important and assists in generating hypotheses and recommendations for further diagnostic evaluation.

Table 32-3
SCHEMA FOR INTERPRETATION OF VFSS

Normal and abnormal anatomy
Normal and abnormal biomechanical movements of structures of the oral pharyngeal swallowing mechanism
Temporal coordination of biomechanical events in relation to bolus flow
Penetration/aspiration
Swallowing efficiency
Evaluation of therapeutic strategies
Changes in bolus volume, viscosity, rate of delivery
Changes in posture
Rehabilitative swallowing maneuvers

Normal and Abnormal Anatomy

Lateral and AP scout films taken prior to fluoroscopy can highlight variations in anatomy that may contribute to the swallowing problem and that may require closer scrutiny. If this is not possible, it is advisable to scan the oral cavity and pharynx fluoroscopically from the lips to the posterior pharyngeal wall, as well as the proximal trachea and esophagus, prior to the administration of contrast. The anatomic configuration of the mandible is observed for evidence of surgical resection and possible plated reconstruction (Fig. 32-3). In addition, gross deviations of mandibular–maxillary relationships are observed. The

VIEW IMAGE

tongue posture is observed at rest and in both lateral and AP projections. Observations can be made about tongue bulk, particularly in the area of the base of the tongue. Asymmetry of the tongue following surgical resection can be appreciated, although accurately differentiating the left from the right side is not possible in the lateral view. Sometimes surgical reconstruction of the tongue has the appearance of normal tongue bulk when in fact a myocutaneous flap is in place and anchors surrounding tissue (Fig. 32-4). In other situations, the tongue bulk may be atrophied, as in the patient with ALS or in a patient who is deconditioned. This may signal impaired bolus formation, control, and propulsion.

The structure of the soft palate at rest is observed for its completeness and bulk. The posture of the soft palate at rest and during speech tasks can provide information about bolus containment before the swallow as well as velopharyngeal sufficiency during swallowing. Palatal appliances should be examined for their purpose. For example, palatal obturators occlude fistulae of the hard palate or the nasopharynx; a palatal lift promotes improved velopharyngeal closure by elevating the soft palate during swallowing; and a palatal reshaping device may augment the contour of the hard and soft palates to form a surface against which the tongue can contact for bolus propulsion. Assessment of swallowing function with and without palatal appliances in position during swallowing may be indicated.

Nasogastric feeding tubes do not need to be removed during the fluoroscopic study, as they usually do not interfere directly with swallowing function. There are three exceptions: firstly, if the nasogastric tube is coiled in the pharynx, it may affect swallowing efficiency (Fig. 32-5); secondly, increased pharyngeal retention may be observed if the bore of the feeding tube is large and the tube itself is rigid in the context of a weakened swallow; and thirdly, if the feeding tube is located in the midline postcricoid region such that the arytenoid cartilages are stented open, and complete rotation of the cartilages and adduction of the vocal folds are restricted. This last scenario can best be appreciated in the AP view. In these cases, it may be wise to remove the nasogastric feeding tube and replace it if necessary after the study.

The epiglottis is observed for signs of surgical resection and evidence of edema or fibrosis as a result of radiation therapy (Fig. 32-6). The relationship of the tongue base to the posterior pharyngeal wall is noted with respect to the area that must be approximated to drive the bolus into the hypopharynx. However, it cannot automatically be assumed that reduced tongue base muscle mass or pharyngeal soft tissue at rest, that is, a vacuous pharyngeal lumen, will not adduct completely during swallowing. Sometimes compensatory pharyngeal wall adduction is observed with a reduced

FIGURE 32-5 Nasogastric tube coiled in the hypopharynx.

VIEW IMAGE

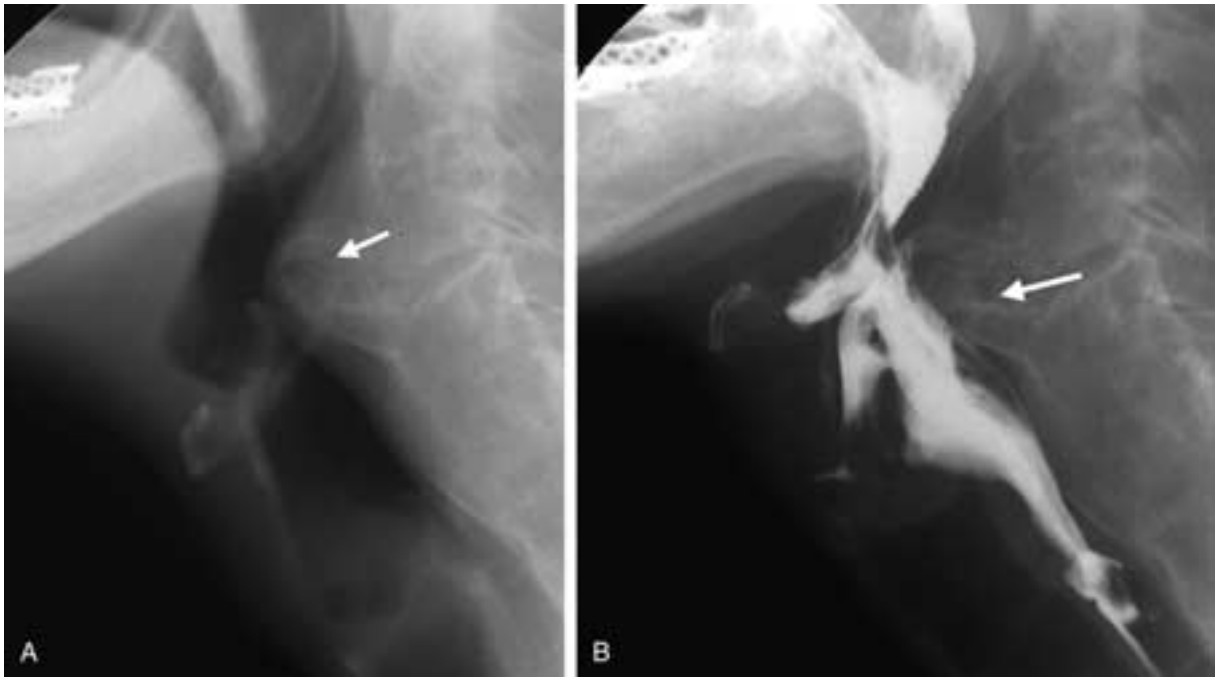
FIGURE 32-6 Radiation effects on structures of the hypopharynx, epiglottis, and arytenoid cartilages. The posterior pharyngeal wall is thickened (*arrow*).

tongue base mass, as occurs in patients with tongue base resections from carcinoma. In patients who have had pharyngeal resections with flap reconstructions, a soft-tissue fullness is seen, often simulating the pharyngeal constrictor muscles. However, the flap is bulkier than the normal pharyngeal muscles, and there is no observed contraction of the flap during swallowing.

The contour of the cervical spine is well appreciated in the lateral projection, and note is taken of the location and size of cervical osteophytes (Fig. 32-7A). Approximately 20% to 30% of the elderly population present with diffuse skeletal hyperostosis (DISH) manifesting as cervical osteophytes at C5-C6 and of these, 28% complain of symptoms of dysphagia.[40, 41] Osteophytes, if sufficiently large, may impinge directly on the cervical esophagus and hypopharynx, allowing only squirts of the bolus to pass. Periosteophytic edema or inflammation may increase the dysphagia. Osteophytes can coexist with reduced laryngeal closure and may additively cause more severe dysphagia than if either is present alone (Fig. 32-7B). It is important to resist the temptation to implicate the osteophyte solely as the predominant etiology of the swallowing difficulty, particularly in acute-onset dysphagia. Osteophytes develop over time, and most patients adapt unconsciously to their presence. In patients who have had surgery or radiation therapy that restricts the motion of the hyoid bone (and thus of the larynx), the coexistence of pronounced osteophytes can be a cause of dysphagia. Other causative biomechanical factors should be considered in these cases, such as weak laryngeal excursion or impaired tongue base retraction, particularly since surgical reduction of osteophytes is a risky and complex procedure. Valadka et al.[41] illustrate this point very clearly in a report on a patient who underwent resection of an anterior cervical osteophyte for relief of dysphagia after two separate diagnostic evaluations by two different otolaryngologists failed to detect base of tongue cancer.

Some patients have undergone cervical fusion procedures



VIEW IMAGE

FIGURE 32-7 **A**, Cervical osteophyte (*arrow*) and its effect on swallowing, with inhibited epiglottic deflection and laryngeal closure resulting in aspiration. **B**, Osteophyte (*arrow)* aspiration is observed during the swallow as a result of restricted epiglottic deflection and hyolaryngeal excursion.

with autologous grafts or rod placements. These patients may present with hematoma formation, edema, infection, and denervation with injury to the recurrent laryngeal nerve as a result of the surgical necessity of shifting structures across the midline to reach the cervical spine. Usually the pharyngeal edema subsides within a few days of surgery; however, if severe, the pharyngeal contraction waves and bolus clearance, particularly during swallowing of solid foods, may be temporarily compromised. If fibrosis affects the pharyngeal constrictor muscles, poor pharyngeal contraction can be permanent. Increased prevertebral space soft tissue that is observed in patients treated with radiation therapy and/or chemotherapy for hypopharyngeal tumors subsides more slowly but has the same impact on the swallow. It is not uncommon to observe pharyngeal wall edema in these patients months after radiation therapy is completed, as seen in Figure 32-8.

The pharyngeal recesses form the conduit for bolus flow, and their capaciousness or lack thereof can assist in compensating for disordered pharyngeal contractions. For example, patients with recent pharyngeal wall resections may display edema such that the pyriform sinuses are unable to contain even a small amount of residue after the swallow, and this may lead to prompt aspiration. On the other hand, patients with generalized deconditioning and muscle wasting in the pharynx may present with generous pyriform sinuses that can contain considerable residue that does not empty into the laryngeal vestibule.

Calcifications of the laryngeal cartilages, carotid arteries, and various ligaments appear as areas of radiodensity at fluoroscopy and on x-ray films. Taking note of these areas prior to the administration of contrast will eliminate the misinterpretation of these sites of calcification as droplets of barium. This can decrease the overdiagnosis of laryngeal aspiration.

FIGURE 32-8 Severe edema of the posterior pharyngeal wall (*ppw*) and blunting of the epiglottis (*e*) in a patient 3 months after receiving radiation therapy for a pharyngeal tumor.

VIEW IMAGE

FIGURE 32-9 Stricture (*arrow*) of the cervical esophagus after laryngectomy.

VIEW IMAGE

The presence of a laryngectomy must be noted. These patients are generally not at risk for aspiration of contrast; however, they may present with bolus hesitation as a result of strictures at the surgical site, scarring or resection of the hyoid-related musculature, or as a result of radiation therapy (Fig. 32-9).

Vocal fold adduction is best observed in the AP projection. Glottic closure, as discussed previously, is critical for swallowing, and even cursory evaluation of vocal fold movements during phonation is helpful in determining the risk of aspiration and the presence of vocal fold asymmetry. However, the diagnosis of vocal fold paralysis should be made with caution, as image clarity can be obscured by the vocal folds superimposed on the dense bony structure of the cervical spine. Videofluoroscopy does not provide a detailed view of the laryngeal structure because of the poor resolution of the cartilaginous structures. Sometimes contrast present in the airway outlines the laryngeal structures more clearly and provides information about arytenoid cartilage edema, surgical resection, the contour of the aryepiglottic folds, and the amount of tracheal aspiration.

Patency of the airway should be appreciated and the presence of a tracheostomy tube noted. Tracheal or supraglottic stents may be present, and their location in the trachea should be noted, as at times the superior edge of the upper limb of a T-tube stents open the glottis, affecting airway protection. In most cases, however, sufficient superior and hyolaryngeal excursion prevents aspiration of contrast of certain consistencies. Unless the patient is mechanically ventilated, it is advisable to have the patient

Copyright © 2003, Mosby, Inc. All rights reserved.

swallow with the tracheostomy tube cuff deflated. Ideally, the tracheostomy tube should have a diameter that permits airflow around the tube in the trachea such that finger occlusion of the hub of the tube or capping is possible. A one-way speaking valve may also be used, allowing inhalation through the tracheostomy tube and exhalation through the oral cavity as the one-way valve closes. Closure of the vocal folds at the glottis permits a strong clearing cough if the patient aspirates. A cursory appreciation of the underlying anatomic variations allows the clinician to develop hypotheses about the potential swallowing problem and to speculate, at least in part, about the possible risks of performing the swallowing study.

Normal and Abnormal Biomechanical Movements

Lips and Cheeks

The lips must close around the spoon or cup in order to contain the bolus in the oral cavity. Lip protrusion is necessary for straw drinking. While lip seal functionality can readily be observed during the clinical swallowing evaluation, the ease with which the bolus is accepted can affect tongue posturing. Contraction of the buccinator muscles together with lip closure and tongue tip contact against the alveolar ridge facilitates cohesive bolus formation in the oral cavity. Weak lip closure may result in loss of the bolus anteriorly from the oral cavity, as in drooling. Absent lip and jaw closure occurs in patients with bulbar ALS and affects containment of saliva as well as food and contrast. Sometimes drooling occurs because of reduced sensation of the lips as well as reduced motor output. Resection of mandibular tumors or even lingual cancers necessitates mandibulotomy, severing the labial branch of the alveolar nerve and affecting awareness of lip closure, and resulting in lack of awareness of saliva or contrast on the lips or chin. In patients with facial droop, for example as a result of unilateral middle cerebral artery distribution cerebrovascular accident or acoustic neuroma resection affecting facial nerve function, the bolus may fall immediately into the lateral buccal sulcus of the affected side, where it pools.

Tongue

Movement of the tongue plays a central role in swallowing. Its function is to manipulate the bolus, position it carefully, and propel it from the oral cavity into the pharynx. There is a great deal of normal variability in bolus formation and propulsion. Dodds et al.[42] identified two types of oral swallowing events. In the first type, *tipper* swallows, the bolus is positioned on the dorsum of the tongue and the swallow is initiated with the tip of the tongue against the incisors (Fig. 32-10). In the second type, *dipper* swallows, the bolus is held under the tongue in the anterior sulcus of the floor of the mouth, and the tongue tip must scoop up the bolus and elevate it onto the tongue before swallowing. Dodds et al.[42] observed dipper swallows more commonly in older individuals. Furthermore, some normal individuals take large sips and bites and swallow large mouthfuls at once; others segment the bolus into distinct portions and swallow small amounts. In normal individuals, formed

VIEW IMAGE

liquid boluses are identified radiographically in the lateral projection as elliptically shaped entities contained on the tongue dorsum, prevented from spilling into the pharynx by depression of the soft palate against the back of the tongue (contraction of the palatoglossus muscle). In the AP projection, the bolus is seen enclosed in a central groove on the tongue dorsum, with the buccinators contracted against the dental ridges and the lateral borders of the tongue in contact with the alveolar ridge (Fig. 32-11).

During mastication, the material is placed on the tongue and the midline and lateral borders of the oral tongue move the bolus toward the dental arches. In the AP view, opening and closing of the jaw enables rotary tongue movements to the left and right. Frequently, some of the bolus spills into the lateral sulci but most normal individuals can sweep the sulci clean with the tongue tip and lateral borders and reassemble the bolus ready for swallowing. The palatoglossal seal observed in liquid and semisolid bolus manipulation is broken in mastication by the constant movements of the posterior tongue. Therefore, it is not unusual for the head of the bolus to be seen moving toward the vallecular space while mastication and bolus formation are in progress. If leakage of the bolus is observed during formation of semisolids or liquids, it is referred to as premature spillage and is an indication of muscle weakness either in the tongue or in the palatoglossus muscle. The risk is that the material will spill into the open airway and be aspirated prior to the onset of the pharyngeal swallow response. Once the bolus is formed, a series of wave-like movements of the tongue dorsum creates pressure on the bolus and propels it with a piston-like motion[21, 22] from anterior to posterior against the hard and soft palates toward the oropharynx. The tongue base depresses and moves anteriorly, forming a ramp or chute down which the bolus flows. The posterior tongue movement continues with the tongue base contacting the

posterior pharyngeal wall, helping to direct the bolus toward the vallecular space (Fig. 32-12). In the AP view, bolus propulsion is observed as cohesive midline bolus flow.

Abnormalities in swallowing resulting from impaired tongue function can affect the passage of the bolus to a minor or major degree. The most extreme impairment in tongue function is observed in patients with total reduction in tongue bulk and hence movement, as in total glossectomy, or marked lingual atrophy, as in advanced ALS. These patients present with difficulty positioning the bolus on the tongue, manipulating it, or controlling it for propulsion. In the case of semisolid boluses, videofluoroscopic images reveal stasis of material on the tongue or reconstructed tongue or in the valleculae. Less viscous consistencies fall into the lateral or anterior sulci or spill in an uncontrolled fashion into the pharynx. Mashing of the tongue against the palate or vertical movements of chewing lacking rotary actions are inefficient, as the tongue does not draw the bolus together in a cohesive manner. In compensation, the patient may extend the head to enlist the assistance of gravity for bolus propulsion. Sometimes opening and closing the jaw, especially in cases of total glossectomy, where the tongue has been reconstructed with a regional or free myocutaneous flap, helps to compress the bolus against the palate and slowly move it posteriorly to the pharynx. However, in these patients, it is not unusual to observe contrast adhering to the hard palate or coating the dorsum of the tongue. Improved efficiency in bolus propulsion may be observed by following bites of semisolid material with sips of liquids, provided that airway protection is intact. One of the compensatory strategies developed by patients with total glossectomy is what has been referred to as a *dump swallow maneuver*, in which the bolus is swallowed as a result of suprahyoid activity, laryngeal closure, and pharyngeal shortening. Mastication of solid boluses is unrealistic in these patients, as deforming the solid, mixing it with saliva, and reforming it are not possible. These patients are in danger of aspirating large, unmasticated boluses.

Partial glossectomy can have a profound effect on bolus control, manipulation, and deformation. The location of the resection and nature of reconstruction will dictate the nature and severity of the impairment and the location of the residue. The effects of structural changes can be variable and wide-ranging even among patients with similar operative procedures and radiation treatments. Patients with anterior oral tongue glossectomy crossing the midline or with floor of mouth resection have the greatest challenge in holding the bolus cohesively for propulsion. These patients display a marked amount of residue in the oral cavity and require head extension or careful placement of the bolus in the posterior pharynx. During VFSS it may be helpful to bypass assessment of the oral stage in order to determine pharyngeal swallow impairment by controlled injection of boluses into the pharynx via a catheter or syringe. Once the integrity of the pharyngeal swallow has been established, compensatory strategies increasing bolus volume may be attempted.

Tongue base resections affect tongue base retraction and bolus propulsion through the pharynx and hypopharynx. Disturbance of the suprahyoid musculature that sometimes accompanies these resections affects laryngeal excursion, and therefore epiglottic downfolding and airway protection. The outcome of bilateral tongue base resection may present radiographically as significant residue along the pharyngeal

wall and in the vallecular space, and aspiration may occur before the swallow because of uncontrolled spillage or after the swallow from the residue. Piecemeal swallowing may be observed in which the boluses are purposefully segmented and swallowed in small portions. Multiple swallows of the same bolus is a hallmark behavior of reduced tongue base function.

Patients with hemiglossectomy in which the tongue is resected only on one side may be able to compensate for their defects by containing the bolus on the unaffected side. Functionality, however, will depend on preservation of mobility of the tongue on the unaffected side. If the tongue is tethered in reconstruction by a regional or free flap, or is fibrosed as a consequence of radiation therapy, compensatory behaviors may be restricted. In these cases, residue will be observed along the oral cavity and pharynx in the area of the defect. AP views reveal asymmetric bolus flow very clearly.

The posterior tongue contributes to the glossopalatal seal, which is particularly important during liquid swallows. Compromise of this valve as a result of weakness or resection can result in loss of bolus control, and liquids may be presented prematurely to the pharynx prior to initiation of the pharyngeal swallow response, potentially resulting in aspiration.

Lingual tremors at rest may not result in oral stage swallowing disorders. However, patients with Parkinson's disease or Parkinson-like symptoms may have difficulty initiating bolus propulsion. Overall lingual weakness may co-occur and can manifest in searching movements of the tongue and repetitive small-amplitude AP movements slowly shuffling the bolus toward the pharynx in an action referred to as *tongue pumping*. This behavior mimics the festinating behaviors common in ambulation patterns of patients with Parkinson's disease. These patients may lack the range of motion for coordinated rotary lingual movements and uncontrolled boluses may spill prematurely into the pharynx, resulting in aspiration particularly with liquid contrast. Oral dyskinesia with lingual chorea may be observed in patients with Huntington's disease. In these cases, tongue movements are dyssynchronous, resulting in large bites, poor mastication, and rapid swallowing.[43, 44]

Bilateral tongue weakness can be observed in a variety of conditions, the most common of which is cerebrovascular accident, in which dysarthria and dysphagia are symptomatic. Thin liquids and textured solids present the greatest challenge to these patients, who are unable to cradle the boluses on the tongue or coordinate movements for mastication and run the risk of uncontrolled bolus loss. Limited tongue-driving force results in vallecular retention and weak bolus flow through the hypopharynx, and where sensation is preserved, multiple swallows represent the patient's attempt to clear the residue. Patients with unilateral tongue weakness, as in unilateral stroke or skull base tumors affecting the hypoglossal nerve, may be able to compensate for the weakness by chewing on the contralateral side, albeit in an awkward and protracted fashion. Retrieving boluses from the buccal sulci is complicated and may require digital removal.

Efficiency of swallowing can be affected by the habitual tongue posture. Normally, the tongue moves posteriorly along the palate, driving boluses into the pharynx. Tongue thrusting is a reverse swallow pattern, usually of neurologic origin such as in patients with cerebral palsy, in which the tongue thrusts forward between the incisors, pushing the food out of the mouth. Usually mastication as well as swallowing is affected in these patients.

Radiation therapy for oral cavity, pharyngeal, and laryngeal tumors carry the side effect of xerostomia, or dry mouth, and tongue function during swallowing can be disturbed as a result of radiation therapy alone. Reduced volume and consistency of saliva affect the ease of bolus formation, particularly with more solid textures, and can result in residue on the tongue or palate. In addition, the speed of tongue movement can be reduced in these patients as a result of tissue fibrosis, a condition that can occur immediately after radiation therapy or even a year after radiation treatments are completed.[9]

Soft Palate or Velum

The soft palate has two distinct purposes during the swallow. In the oral stage, contraction of the palatoglossus contains the bolus in the oral cavity. Once the pharyngeal swallow response is initiated, the soft palate elevates against the lateral and posterior pharyngeal walls, creating a seal of the velopharyngeal port.

Premature spillage into the pharynx and hypopharynx can occur due to weakness of the palatoglossal seal, increasing the risk of aspiration. As was mentioned earlier, premature spillage can only be considered such during liquid and semisolid bolus preparation, where mastication is not required. There is normal loss of the palatoglossal seal during mastication of solid boluses due to lingual and mandibular movements. Cranial nerve dysfunction or palatal resection can cause premature spillage. Careful inspection of soft palate elevation is required, as sometimes it appears that the soft palate is elevating when in fact the tongue is moving posteriorly, propping up the soft palate.
